We use a trial wave function to study the spin-1/2 Kondo effect of a helical metal on the surface of a three-dimensional topological insulator. While the impurity spin is quenched by conduction electrons, the spin-spin correlation of the conduction electron and impurity is strongly anisotropic in both spatial and spin spaces. As a result of strong spin-orbit coupling, the out-of-plane component of the impurity spin is found to be fully screened by the orbital angular momentum of the conduction electrons.

DOI: 10.1103/PhysRevB.81.235411 PACS number(s): 71.10.-w, 71.27.+a, 73.90.+f, 75.20.Hr

On the surface of a three-dimensional (3D) topological insulator, massless helical Dirac fermions emerge.1 Specific materials of 3D topological insulators have recently been studied and observed.2–5 Interesting properties of these helical Dirac fermions have become a focus of recent studies.6–9 In a helical metal, spins are coupled to momenta so that magnetic properties are expected to be highly nontrivial. Theoretical study on this aspect, however, has so far been limited to the effect of a classical magnetic impurity.10

The low-temperature property of a quantum spin-1/2 magnetic impurity or an Anderson impurity in a conventional metal11 has been an interesting and important problem for decades in condensed-matter physics. The problem has been studied by using the renormalization group,12 the Bethe ansatz,13,14 the 1/N expansion,15,16 and the conformal field theory.17 The phenomenon is a well-known Kondo effect, in which the impurity spin is completely screened by the conduction-electron spins. Because of the coupling between spins and momenta, the Kondo effect in a helical metal will be interesting to be examined. In this paper, we use a variational method to address this problem. We show that the correlation of the impurity spin and the conduction electron spin density is strongly anisotropic in both spatial and spin spaces, in contrast to the isotropic screening in a conventional metal. While the impurity spin is quenched at low temperatures, similar to the usual Kondo problem, the correlation between the impurity spin and the spin of the conduction electrons in the helical metal is significantly reduced. The reduction in the spin-spin correlation in the direction perpendicular to the surface can be shown explicitly to be compensated by the screening of the orbital angular momentum of the conduction electrons. The possible experimental consequences will be briefly discussed.

We consider a spin-1/2 magnetic impurity in a helical metal in a two-dimensional (2D) x-y plane, described by the Hamiltonian

$$H = H_c + H_{\text{mix}} + H_d,$$

$$H_c = \sum_{\mathbf{k}} c_{\mathbf{k}}^\dagger (\hat{H}_{\text{eff}} (\mathbf{\sigma} \times \mathbf{k}) \cdot \hat{z} - \mu) c_{\mathbf{k}},$$

$$H_{\text{mix}} = \sum_{\mathbf{k}} V_{\mathbf{k}} c_{\mathbf{k}}^\dagger d + \text{H.c.},$$

$$H_d = (\varepsilon_d - \mu)(n_d^\dagger n_d) + Un_d^\dagger n_d.$$  

In the above equations, $c_\mathbf{k}$ and $d$ are annihilation operators of the conduction electron with momentum $\mathbf{k}$ and of the $d$ electron at impurity site in the spinor representation, respectively. $\sigma$ are the Pauli matrices, $\mu$ is the chemical potential, and $n_d = d^\dagger d$. $H_c$ describes a helical metal, and $H_d$ is a local impurity Hamiltonian with $\varepsilon_d$ the impurity energy level and $U$ the Coulomb repulsion energy of the two $d$ electrons on the same impurity site. $H_{\text{mix}}$ is a hybridization term between the helical metal and the impurity state.

To start with, let us discuss the simple case $H_{\text{mix}} = 0$ first. In this limit, the helical metal and the impurity state are decoupled. The single electron eigenenergy and its corresponding eigenstate of the helical metal $H_c$ are given by

$$\varepsilon_{\mathbf{k},z} = \pm \hbar v_F |k| - \mu,$$

$$\gamma_{\mathbf{k},z} = \frac{1}{\sqrt{2}} (e^{i/2}\theta_{\mathbf{k}} c_{\mathbf{k}}^\dagger \pm ie^{-i/2}\theta_{\mathbf{k}} c_{\mathbf{k}}).$$

with $\theta_{\mathbf{k}}$ the angle of the momentum $\mathbf{k}$ with respect to the $x$ axis that tan $\theta_{\mathbf{k}} = k_y/k_x$, and “$\pm$” refer to upper and lower bands, respectively. For each single-particle state, its spin lies in the plane and is perpendicular to the direction of its momentum. Note that such a spin-momentum relation has recently been reported in a spin- and angle-resolved photoemission spectroscopy experiment.18 The ground state of $H_c$ is then given by

$$|\Psi_0\rangle = \prod_{\{\mathbf{k},z\} \in \Omega} \gamma_{\mathbf{k},z}^\dagger |0\rangle,$$

where the product runs over all the states within the Fermi sea $\Omega$. As for the impurity part, we shall consider an interesting case, where $\varepsilon_d < \mu < \varepsilon_d + U$, so that the impurity site is singly occupied and has a local moment. The total energy of the system $H_0 = H_c + H_d$ is then
where \( s = \pm \) is the band index and hereafter the sum of \( \{ k \} \) is always over the Fermi sea. In Fig. 1, we illustrate the electron dispersion and the spin of the Dirac fermion and the ground state of a helical metal, in the absence of the hybridization with the impurity state.

To study the ground state of the problem in the conventional metal\(^{16,19} \) or in an antiferromagnet.\(^{20} \) For simplicity, we consider here the large \( U \) limit and exclude the double-\( d \)-electron occupation at the impurity site. We expect the qualitative physics should apply to the case of finite but large \( U \). The trial wave function for the ground state is

\[
\Psi = \left( a_0 + \sum_{\{ k \} \neq 0} a_{k} d_{s_{k}} \gamma_{k} \right) |0\rangle,
\]

where \( d_{s_{k}} = \frac{1}{\sqrt{2}} (e^{i s_{k} \theta_{k}} a_{s_{k}}^{\dagger} - e^{-i s_{k} \theta_{k}} a_{s_{k}}) \), and \( a_{0} \) and \( a_{k} \) are variational parameters. They are to be determined by optimizing the ground-state energy. Note that by construction, the impurity state is either singly occupied or nonoccupied.

The energy of \( H \) in the variational state \( |\Psi\rangle \) is given by

\[
E = \sum_{\{ k \} \neq 0} (E_{0} - \epsilon_{k}) a_{k}^{2} + 2 V_{0} a_{0} a_{k} + \epsilon_{k} a_{k}^{2} + \sum_{\{ k \} \neq 0} \sum_{\{ k \} \neq 0} \epsilon_{k} a_{k}^{2}.
\]

The variational method leads to the equations below

\[
E = \sum_{\{ k \} \neq 0} \epsilon_{k} a_{k}^{2} = \sum_{\{ k \} \neq 0} V_{0} a_{k} a_{k}^{\dagger},
\]

\[
E = E_{0} + \epsilon_{k} a_{k}^{2} = V_{0} a_{k} a_{k}^{\dagger}
\]

which may determine the binding energy \( \Delta_{b} = E_{0} - E \) due to the hybridization

\[
\epsilon_{d} - \mu - \Delta_{b} = \sum_{\{ k \} \neq 0} \frac{|V_{k}|^{2}}{\epsilon_{k} - \Delta_{b}}.
\]

If \( \Delta_{b} > 0 \), the hybridized state is stable against the decoupled state. To proceed further, we introduce an energy cutoff \( \Lambda \) for the hybridization with the impurity state. In our analysis, and consider \( V_{k} = \theta \Lambda - \hbar v_{F} |k| \), where \( \theta \Lambda \) is a step function, which is 1 for \( x > 0 \) and 0 for \( x < 0 \). The low-energy physics is expected to be insensitive to the cutoff \( \Lambda \). A natural energy cutoff for the hybridization in the topological insulator is the half of the bulk gap.\(^{5} \) Equation (7) enables us to determine the ground-state energy \( E \) or the binding energy \( \Delta_{b} \) and the ground-state wave function. The results are that the hybridization always leads to a binding \( \Delta_{b} > 0 \), and a magnetic screening of the conduction electrons to the impurity spin at any \( \mu \neq 0 \). At the Dirac point \( \mu = 0 \), the binding and screening only occur at the dimensionless hybridization strength \( \alpha = \frac{2 \pi \hbar v_{F}}{k_{F}^{2}} \) above a critical value. We will come back to this point later.

We shall first examine the magnetic properties of the system, which are most interesting. The central quantity we will examine is the correlation function of the impurity spin \( S_{\alpha} \) at the impurity site (set to be at the origin \( \mathbf{r} = 0 \)) and the conduction electron spin density \( \mathbf{S}_{e} = \frac{1}{2} \mathbf{c}^{\dagger}(\mathbf{r}) \mathbf{c}(\mathbf{r}) \) in the ground state, namely

\[
J_{u v}(\mathbf{r}) = \langle S_{\alpha}^{u}(\mathbf{r}) S_{\alpha}^{v}(0) \rangle,
\]

where \( \langle \rangle \) is the ground-state average of \( Q \) and \( u, v = x, y, z \) are the spin indices. If \( u, v \) are both on the \( x-y \) plane, we then have, by the rotational symmetry, \( J_{u v}(\mathbf{r}) = J_{u v}(\mathbf{r}^{\prime}) \), if \( u^{\prime} = R_{z}(\beta) u, v^{\prime} = R_{z}(\beta) v \), and \( \mathbf{r}^{\prime} = R_{z}(\beta) \mathbf{r} \), with \( R_{z}(\beta) \) a rotational operator of angle \( \beta \) along the \( z \) axis. \( J_{u v}(\mathbf{r}) \) can be calculated by using the trial wave function in Eq. (3). Note that the variational parameter \( a_{k z} \) is independent of \( \theta_{k} \) since it can be expressed as \( V_{0 a_{0}}(\pm \hbar v_{F} |k| - \mu - \Delta_{b}) \) according to the Eq. (6). In terms of \( a_{k z} \), the diagonal components are found to be

\[
J_{zz}(\mathbf{r}) = -\frac{1}{8} |\mathbf{B}(\mathbf{r})|^{2} + \frac{1}{8} |\mathbf{A}(\mathbf{r})|^{2},
\]

\[
J_{xx}(\mathbf{r}) = -\frac{1}{8} |\mathbf{B}(\mathbf{r})|^{2} - \frac{1}{8} \text{Re}[\mathbf{A}(\mathbf{r})^{2}],
\]

\[
J_{yy}(\mathbf{r}) = -\frac{1}{8} |\mathbf{B}(\mathbf{r})|^{2} + \frac{1}{8} \text{Re}[\mathbf{A}(\mathbf{r})^{2}],
\]

where \( \mathbf{A}(\mathbf{r}) = \sum_{\{ k \}} e^{-i k \alpha} a_{k} \mathbf{c}^{\dagger} \mathbf{d}(\mathbf{k}) \) and \( \mathbf{B}(\mathbf{r}) = \sum_{\{ k \}} e^{-i k \alpha} a_{k} \mathbf{c}(\mathbf{k}) \). \( J_{xx}(\mathbf{r}) \) is rotational symmetric around the impurity site while \( J_{yy}(\mathbf{r}) \) and \( J_{yy}(\mathbf{r}) \) are highly anisotropic in space. In Fig. 2, we show \( J_{xx}(\mathbf{r}) \) and \( J_{yy}(\mathbf{r}, x, 0) \). Note that \( J_{xx}(x, 0) = J_{xx}(x, 0) \) and their signs oscillate in space. A negative (positive) value means antiparallel (parallel) correlation between the impurity spin and the conduction electron spin density. Due to the absence of the spin \( \text{SU}(2) \) symmetry, the off-diagonal components are not zero in general and they are

\[
J_{xy}(\mathbf{r}) = J_{yx}(\mathbf{r}) = -\frac{1}{8} \text{Im}[\mathbf{A}(\mathbf{r})^{2}],
\]

The conduction electron spin is not a good quantum num-

ber in a helical metal. To better understand the Kondo 

screening is zero. The spin-spin screening comes from the 
in-plane spin components. Since 

I is independent of any pa-

rameters including the energy cutoff (the only requirement is 

μ < 0), we expect that this is a general property of the helical 
metal. When the Fermi level is above the Dirac point, there is 
a deviation from the above result. For instant, with the 
parameters 

μ = 0.01A and 

Δρ = 0.005A the deviation is about 

60% of 

1/4. At 

μ > 0, the upper Dirac cone is partially 

filled. The electron state in the upper Dirac cone has spin 
orientation opposite to the corresponding state in the lower 
Dirac cone, which provides a stronger screening than 
induced by the lower band only. We remark that the difference 
between 

μ < 0 and 

μ > 0 is due to the particle-hole asymmetry 
in our model parameter with 

U large. If 

U + 2(eF - μ) = 0, we have particle-hole symmetry, and we expect corresponding 
symmetries for 

μ < 0 and 

μ > 0.

The conduction electron spin is not a good quantum num-

ber in a helical metal. To better understand the Kondo 
screening in the helical metal, we shall consider contribution from the 
orbital angular momentum. Because of the two dimen-
sionality, only 

component of the orbital angular mo-
moment can be considered here. The system is invariant with 
respect to a simultaneous rotation of both spin and space 
along the 

axis at the origin of the impurity site. Therefore, 
the 

component of the total angular momentum 

F = 

commutes with the Hamiltonian 
and is a good quan-
tum number, where $L_z$ is the total orbital angular moment of the conduction electrons. Since the ground state preserves the time-reversal symmetry, we have $J^f|\Psi_0=0$. Because of this and $\langle S_z^x S_z^y \rangle=0$ discussed above, we have

$$\sum_{|k\rangle} a_{kz}^2 \frac{\langle L_z^2 \rangle = \langle J^f S_z^z - S_z^x S_z^y - (S_z^x)^2 \rangle }{\sum_{|k\rangle} a_{kz}^2 \langle S_z^x \rangle} = -\frac{1}{4}. \quad (9)$$

Therefore, although spin-spin screening in the $z$ direction in the present Kondo problem vanishes, the orbital angular momentum $L_z$ replaces the role of the conduction electron spin $S_z$ to screen the impurity spin.

The spatial anisotropic correlations may be detected in spin-resolved scanning tunneling spectroscopy experiments. The magnetic susceptibility is finite in this variational theory. In the light of the unconventional spin correlations, exactly how the susceptibility behaves has to be answered by more elaborate treatments such as quantum Monte Carlo and numerical renormalization group. This issue is left for further investigations.

We now discuss the binding energy $\Delta_b$ of the system. From Eq. (7), we obtain

$$\epsilon_d - \mu - \Delta_b + \alpha(\Lambda - |\mu|) = \alpha(\mu + \Delta_b) \ln \frac{4(\Lambda + \mu + \Delta_b)\Lambda}{(\mu + |\mu| + 2\Delta_b)^2}. \quad (10)$$

In the limit of small $\alpha$, and $\alpha\Lambda < \mu - \epsilon_d$, we have

$$\Delta_b \approx \Lambda \exp \left[ -\frac{\mu - \epsilon_d - \alpha\Lambda}{\alpha|\mu|} \right], \mu < 0,$$

$$\Delta_b \approx \frac{\mu^2}{\Lambda} \exp \left[ -\frac{\mu - \epsilon_d - \alpha\Lambda}{\alpha|\mu|} \right], \mu > 0. \quad (11)$$

If the Fermi level is at the Dirac point, $\mu=0$, $\Delta_b$ has a positive value solution only if $\alpha > \alpha_c = |\epsilon_d|/\Lambda$. In other words, for a given hybridization strength $\alpha$, there is a critical value of the impurity $d$ level, below which there is no magnetic screening. This is due to the vanishing density of states at the Dirac point. This result is similar to the impurity problem in graphene.\textsuperscript{21,22} The binding energy as functions of the chemical potential $\mu$ and the hybridization $\alpha$ are plotted in Fig. 4.

$\Delta_b$ is asymmetric about the point $\mu=0$. The solid curves in Fig. 4 are for $\alpha=\alpha_c$ and $\mu=0$, respectively. At $\alpha > \alpha_c$, the hybridized state is always stable. At $\alpha < \alpha_c$, the binding energy is strongly reduced around the Dirac point and vanishes at $\mu=0$. As $\alpha \rightarrow \alpha_c + 0^+$, $\Delta_b \approx |\alpha - \alpha_c|/\Lambda$. This behavior is consistent with the result by using large-degeneracy method.\textsuperscript{23}

In summary, we have examined a spin-1/2 Anderson impurity in a 2D helical metal. The momentum-dependent spin orientation in the helical metal shows interesting magnetic properties. We have used a trial wave-function method to study the system at the large Coulomb $U$ limit. While the impurity spin is quenched by the conduction electrons, we find strong spin and spatial anisotropies in the correlations between the impurity spin and the conduction electron spin density. Because of the strong spin-orbit coupling, the orbital angular momentum also contributes significantly to the screening of the impurity spin. In particular, the out-of-plane component of the impurity spin is found to be fully screened by the orbital angular momentum of the conduction electrons. After our paper was submitted, there was a report on the experimental realization of the magnetic doping on the surface of the 3D topological insulator Bi2Se3,\textsuperscript{24} and a e-print by Zitko, who studied the essentially the same model as ours and mapped it onto a conventional Anderson pseudogap impurity model.\textsuperscript{25} He showed that the impurity spin is fully screened. Our trial wave-function method reported here is consistent with his result.

Finally we comment on the similarity and difference of the helical metal with the graphene. In terms of the eigenenergy problem, a helical metal is often considered to be a quarter of a graphene, where the pseudospin plays the similar role with the spin in helical metal. The graphene has a twofold spin degeneracy and twofold degeneracy associated with the two sublattices. Our results for the binding energy are similar to the graphene. However, because of the difference between the spin in the helical metal and the pseudospin in graphene, the magnetic properties of the two are different. If we consider only one of the two Dirac cones is coupled to the spin-1/2 impurity, the graphene behaves like a conventional metal.

We acknowledge useful discussions with Yi Zhou and Naoto Nagaosa, and acknowledge partial support from HKSAR and RGC. Q.H.W. was supported by NSFC (under Grants No. 10974086 and No. 10734120) and the Ministry of Science and Technology of China (under Grant No. 2006CB921802).
