Common association of haemolytic uraemic syndrome with invasive Streptococcus pneumoniae infection in five Chinese paediatric patients

Haemolytic uraemic syndrome is an important cause of acute renal impairment in childhood. We review the incidence, and clinical and laboratory features of haemolytic uraemic syndrome in a Chinese population. Five patients were identified from 2006 to 2008. All patients were young children with associated invasive Streptococcus pneumoniae pulmonary infection. Serotypes 3, 14, and 19A were confirmed in four patients. The classical post-diarrhoeal form associated with Escherichia coli (O157:H7) infection was not seen. One patient died of acute respiratory failure. Streptococcus pneumoniae infection, as an associated condition in haemolytic uraemic syndrome, is important and relatively common in Chinese patients, especially among children. The acute clinical picture is similar to that reported in the western literature, except for an uncommon association with meningitis. The medium-term renal outcome of the Chinese population appears to be more favourable than the Caucasians. Widespread vaccination against Streptococcus pneumoniae may have resulted in changes in bacterial epidemiology and clinicians should be continuously aware of this severe disease. The use of washed blood components for transfusion in the acute stage requires further study.

Introduction

Haemolytic uraemic syndrome (HUS) classically presents as a post-diarrhoeal disease, and is often associated with Escherichia coli (O157:H7) infection. However, the relative incidence of HUS associated with invasive pneumococcal infection may be underestimated due to lack of awareness, and the incidence may be increasing. Pneumococcal HUS is characterised by T-antigen activation, whereby the enzyme neuraminidase produced by the bacteria cleaves N-acetylmuraminic acid from the glycoproteins on the cell membrane of the red blood cells (RBCs) and glomeruli and exposes the Thomsen-Friedenreich antigen (T-antigen). This desialylation of glycoprotein is thought to be important in the pathogenesis of HUS. Pneumococcal HUS is associated with significant mortality and morbidity in Caucasians. This report is a retrospective review of all patients with a diagnosis of HUS made between January 2006 and December 2008 at the Haematology Division, Department of Pathology, Queen Mary Hospital, Hong Kong. Data on clinical manifestations, laboratory findings and follow-up status were collected from the patients’ medical records and compared with reports in the literature.

Haemolytic uraemic syndrome was defined by a triad of microangiopathic haemolysis, thrombocytopenia, and acute renal impairment. Acute disseminated intravascular coagulation was excluded by the absence of a significantly raised D-dimer level (<8 mg/L). Acute renal impairment was determined by a serum creatinine level above the age-specific reference range in a patient with no known history of renal disease. Neurological signs should be absent unless there was documented evidence of central nervous system infection. T-antigen activation on RBCs was documented by Arachis hypogaea (peanut) lectin agglutination.

Case report

Five patients with HUS were identified, and all were children with invasive Streptococcus pneumoniae respiratory infection (Table). There were two boys and three girls. Their median age was 3 years (range, 2-4 years). Haemolytic uraemic syndrome was diagnosed between 3 days and 11 days after the onset of febrile illness for all patients. Bacteriology was confirmed by positive blood and/or pleural fluid culture (Table). Only one of the isolates was sensitive to penicillin. Serotyping results were available for four patients: type 14 (n=2), type 3 (n=1), and type 19A (n=1). Four of the five patients developed empyema requiring decortication. Two patients received ventilatory support. None of the patients...
Five patients with haemolytic uraemic syndrome (HUS) were reviewed. The clinical features, laboratory findings and outcomes are presented in Table 1.

All patients had impaired renal function as evidenced by a raised serum creatinine level (range, 101-756 μmol/L [reference range, 10-60 μmol/L]). Two patients developed oliguria, one of whom required dialysis for 2 weeks for anuria, fluid retention, and rapidly deteriorating renal function. Profound anaemia and thrombocytopenia were consistent findings. Peripheral blood smear examination revealed RBC fragmentation in all patients, which provided the first clue to the diagnosis (Fig). None of the patients had significant bleeding. The mean nadir haemoglobin level and platelet count was 41 g/L (range, 13-55 g/L [reference range, 95-165 g/L]) and 7 x 10^9/L (range, 4.9-10 x 10^9/L [reference range, 150-400 x 10^9/L]), respectively. The clotting profile was deranged in all patients, as reflected by prolonged activated partial thromboplastin time (range, 56.5-109.0 seconds [reference range, 25.9-33.7 seconds]) and normal-to-mildly prolonged prothrombin time (range, 11.5-20.4 seconds [reference range, 11.3-13.5 seconds]). Fibrinogen was elevated in all patients (range, 4.14-7.66 g/L [reference range, 1.46-3.38 g/L]), partially masking the coagulation defects. In keeping with the clinical picture, evidence of frank disseminated intravascular coagulation was not detected with D-dimer assay at presentation (<8 mg/L in all patients).

T-antigen activation on RBCs was documented in all patients. Direct antiglobulin test was positive for complement with or without immunoglobulin in four patients. All patients received RBC transfusion. Four patients received platelet transfusion for prophylaxis or to cover invasive procedures. Washed RBCs and plasma-reduced platelet concentrates were transfused, except for one patient who was transfused before a diagnosis of HUS was made. This patient had respiratory failure requiring cardiopulmonary resuscitation soon after admission, with an associated rapid drop in haemoglobin level and platelet count.

She received urgent transfusion with unwashed RBCs and ordinary platelet concentrates. She developed disseminated intravascular coagulation and died of refractory septicaemic shock and multi-organ failure a few hours later. This patient had previously received one dose of pneumococcal vaccine. The other four patients had not been vaccinated against pneumococcus.
All four surviving patients had normal serum creatinine (<60 mmol/L), haemoglobin (>100 g/L), and platelet (>150 x 10⁹ /L) levels, and no hypertension, proteinuria, or haematuria during a median follow-up of 31 months (range, 24-48 months).

**Discussion**

Haemolytic uraemic syndrome in Chinese patients is commonly associated with invasive *S pneumoniae* infection. This complication appears to be restricted to the paediatric age-group and is uncommon in adults, probably because T-antigen activation usually occurs in the paediatric age-group. Indeed, all five patients with HUS in this report were young and had severe pulmonary *S pneumoniae* infection. Observation of microangiopathic haemolysis at peripheral blood smear examination and demonstration of T-antigen activation on RBCs provide strong support for the diagnosis of HUS. The acute clinical and laboratory findings in terms of disease onset, pulmonary, renal and haematological manifestations of the patients in this report were similar to pneumococcal HUS reported in both Chinese and Caucasian series, with the exception of an uncommon association with meningitis in Chinese patients. A study of 43 patients from the UK reported an acute mortality rate of 9%, with three of four deaths related to central nervous system involvement.

No documented case of *E coli* (O157:H7) infection and associated HUS has been seen at Queen Mary Hospital from 2003 to 2008. This confirms findings from other reports of Chinese patients, but contrasts with reports from western countries where pneumococcal HUS constitutes 5% or less of all HUS, although an increasing trend has been observed. The marked difference in relative prevalence of *E coli*– and *S pneumoniae*–induced HUS among different ethnic groups is intriguing, and may point to underlying genetic and/or environmental factors affecting disease susceptibility.

In the largest reported series of pneumococcal HUS, renal morbidity at a median follow-up of 9

months was considerable, with 10 of 35 patients showing evidence of renal dysfunction as evidenced by raised serum creatinine level, proteinuria, and/or hypertension. In contrast, the prognosis for renal recovery appears to be favourable for Chinese patients. Two Chinese studies reported complete renal recovery with no evidence of chronic sequelae. The surviving patients in this series also had a normal serum creatinine level with no hypertension or proteinuria at a median follow-up of 31 months. Longer follow-up will confirm whether this renal status remains stable.

Different serotypes of pneumococcal HUS have been implicated in pneumococcal HUS. Serotype 14 is seen in most series but the most prevalent serotype varies among populations. Interestingly, the widely used 7-valent pneumococcal conjugate vaccine (serotype 4, 6B, 9V, 14, 18C, 19F, 23F) does not include most of the serotypes isolated in pneumococcal HUS in a recent UK study. In particular, serotypes 3 and 19A are not covered. Serotype 19A was the most prevalent in the UK study, reflecting its increasing prevalence in the paediatric age-group since the introduction of the 7-valent vaccine in the US. Serotype 19A is also not covered by the 9- or 11-valent pneumococcal vaccines, and pneumococcal HUS associated with serotype 19A is increasingly being reported. The same epidemiological change in pneumococcal infection has been observed in Chinese populations. A large epidemiological study of serotype distribution of invasive *S. pneumoniae* isolates collected from children in Hong Kong between 1995 and 2001 showed that serotypes 6B, 9V, 14, 18C, 19F, and 23F together constituted 90% of all isolates. As serotype 19A was not detected in any isolate, good protection from the 7-valent vaccine could be expected. However, serotype 19A has recently become more prevalent in China in children younger than 5 years. The data from this report showed that serotypes 3 and 19A were present among patients with pneumococcal HUS. A study from Taiwan also detected the occurrence of serotype 3 in patients with pneumococcal HUS. A pneumococcal vaccination programme using the 7-valent vaccine has been implemented in many countries, including Hong Kong. Post-vaccine surveillance is therefore important to monitor any increase in invasive *S. pneumoniae* infection and pneumococcal HUS due to infection by serotypes not covered by the vaccine.

T-antigen activation is demonstrable in all patients with pneumococcal HUS. As anti-T antibodies are present in the plasma of almost all adult blood donors, washed RBCs and plasma-reduced platelets are routinely used for patients with pneumococcal HUS to reduce the risk of iatrogenic haemolysis caused by antigen-antibody interaction. However, the necessity of these measures has not been studied and remains controversial. It should be noted that anti-T antibody does not fix complement in vitro. There is evidence from animal studies that pneumococcal HUS is common in Chinese populations. Two Chinese studies reported incidence data on pneumococcal HUS in children could be expected. However, serotype 19A has been implemented in many countries, including Hong Kong. Post-vaccine surveillance is therefore important to monitor any increase of invasive *S. pneumoniae* infection and pneumococcal HUS due to infection by serotypes not covered by the vaccine.

Acknowledgements

The authors thank the Hong Kong Red Cross Blood Transfusion Services for performing T-antigen activation tests and Dr Samson Wong, Department of Microbiology, Queen Mary Hospital, for providing incidence data on *Escherichia coli* (O157:H7) infection.
