§ Department of Computer Science, The University of Hong Kong

Abstract—NanoNets are networks of nanomachines at extremely small dimensions, on the order of nanometers or micrometers. Recent advances in physics and engineering have made basic computing and communication feasible on nanomachines, and NanoNets are envisioned as an important emerging technology with broad future applications. Traditional networking solutions require significant modifications for application in NanoNets. In this paper, we focus on routing algorithm design in NanoNets. Based on the salient features of a NanoNet, including low node cost and very low available power, we propose a new routing paradigm for multi-hop data transmission in NanoNets. Our design, termed Buddy Routing (BR), is enabled by latest advancements in physical layer network coding, and argues for pair-to-pair data forwarding in place of traditional node-to-node data forwarding. Through both analysis and simulations, we compare BR with point-to-point routing, in terms of raw throughput, error rate, energy efficiency, and protocol overhead, and show the advantages of BR in NanoNets.

I. INTRODUCTION

NanoNetworks represent an emerging type of wireless sensor networks consisting of nanonodes—wireless nodes at extremely small form factors, on the order of micrometers or nanometers. This work aims to present the first routing/MAC protocol design tailored for multi-hop NanoNets, by utilizing physical layer network coding (PNC) for pair-to-pair routing that break through the frugal nodal power limitation at nanonodes.

As shown in Fig. 1, the structure of a nanonode resembles that of a wireless sensor node to a great extent. Recent advances in physics and engineering technologies have made it possible to manufacture storage, processor, radio antenna and power supply at the nano-scale [1], [2]. For example, a typical nanotube based transmitter has a volume of $3.9 \times 10^4 \text{ nm}^3$ [3]. Electromagnetic communication between nanonodes can be enabled by either frequency modulation or phase modulation. Such invisibly small nanonodes can be easily attached to everyday objects or human bodies, for sensing antigen molecules, the immune system, or other physical parameters of interest.

Compared with a wireless mesh network and a ‘regular’ wireless sensor network, a NanoNet has a number of salient features. Nanotube radiation is at Terahertz domain, leading to wavelengths on the order of 0.1 mm, and usually travels in line-of-sight fashion. Nano-processors, nano-tranceivers and nanopower supply are usually orders of magnitude weaker than their counterparts in wireless mesh networks. Due to limitations in nano-battery technologies, power supply is weak and short-lived, e.g., providing current at $45 \mu A$ per cm$^2$-μm, and requiring periodical recharges [1], [4]. Consequently, direct nano communication can only happen in very short distances, and at very low rates. In short, NanoNets present an entirely new networking paradigm that invites radical revolutions in networking solutions, including error detection/correction, routing and MAC algorithms [5].

By grouping nodes into collaborating pairs, pair-to-pair forwarding can break through the fundamental nodal power constraint, enhancing the communication range and rate of nanonodes, and is therefore a promising paradigm for exploration in routing algorithm design for NanoNets. Such routing algorithms are best coupled with a simple MAC algorithm, such as TDMA, so that execution on nano processors does not become a bottleneck.

Collaborative data forwarding among paired nanonodes can be enabled by two different physical layer techniques: amplify&forward (A&F), or physical layer network coding (PNC) [6]. A detailed comparison between the two, in terms of error rate and capacity, is provided in Sec. II. We choose PNC for its potential in higher communication rate. PNC is a recent technology that views the overlap of analog signals in the air as linear combination of source signals. PNC based mapping and demodulation can be applied to decode for a digital version of the linear combination [6], [7].

Fig. 2 illustrates how PNC can enable pair-to-pair data forwarding that underlies our proposal of Buddy Routing (BR). Assume the source packet $x$ for transmission is broken into two equal-length sub-packets $x_1$ and $x_2$. We pair up each of the Tx node and Rx node with a nearby ‘buddy’ node. The Tx node shares $x_1$ with its buddy, through a short intra-pair transmission. Next, the two Tx nodes simultaneously transmit $x_1$ and $x_2$ respectively to the two Rx nodes, such that their signals are aligned at the buddy node ($N1$) in the Rx pair, which performs PNC to demodulate $x_1 + x_2$, and forwards it to the Rx node.
The Rx node can recover the original packet $x$ from the analog signal it receives, $h_{12}a_1x_1 + h_{22}a_2x_2$, and the encoded packet from its buddy, $x_1 + x_2$, e.g., through an adapted version of Maximum-Likelihood (ML) decoding [7]. Higher communication rate is targeted for data sharing within each pair, with a higher modulation rate. For example, BPSK modulation can be applied for the inter-pair transmission, and 16QAM for intra-pair.

Our main proposal, Buddy Routing (BR), is a PNC-enabled pair-to-pair routing solution, coupled with a tailored and streamlined TDMA MAC for simplicity and efficiency. Targeting multi-hop data routing, we design and present the pipeline operation for data forwarding along a BR route. Through theoretical analysis, we obtain insights on the effect of key parameter selection on the performance of BR. We extend the geographical greedy routing algorithm [8] to its pair-to-pair forwarding version, for computing a BR unicast route. Iterative MAC layer optimization, over both Tx power at nanonodes and lengths of time slots in the TDMA MAC are refined, for mitigating bottleneck interference and end-to-end capacity improvement. Simulation results verify the theoretical analysis that BR has a potential to substantially improve the end-to-end throughput of traditional point-to-point routing.

To our knowledge, BR represents the first multi-hop routing algorithm design for NanoNets, as well as the first such algorithm that leverages PNC in collaborative multi-hop routing. We believe that BR has a potential to breakthrough the power supply bottleneck in NanoNets and smart dust [9] that are formed of extremely small and extremely weak wireless nodes, especially when coupled with a simple and efficient MAC protocol, such as TDMA.

The rest of the paper is organized as follows. Sec. II compares A&F and PNC as the underlying enabling technology for buddy routing, and demonstrates the overall advantage of the latter. Sec. III performs theoretical analysis on the capacity and power efficiency of BR routing. Sec. IV presents a detailed BR-unicast solution, including both the routing and MAC modules, with simulation studies. Sec. V concludes the paper.

II. ENABLING BUDDY ROUTING: PNC vs. AMPLIFY&FORWARD

The pair-to-pair forwarding gadget depicted in Fig. 2, underlining the idea of Buddy Routing, can be enabled by either PNC or Amplify&Forward (A&F). A number of virtual MIMO forwarding schemes recently proposed are in essence based on A&F-enabled collaboration [10], [11]. The main difference between PNC and A&F lies in the intra-pair transmission to the Rx node from its buddy: in PNC, the Tx buddy transmits a digital version of $x_1 + x_2$; in A&F, it transmits an amplified version of the received analog signal $h_{11}a_1x_1 + h_{22}a_2x_2$.

In this section, we compare these two enabling technologies in terms of multi-hop throughput potential (II-A), single-hop BER (II-B), and protocol overhead.

A. PNC vs. A&F: Multi-hop Buddy Routing

In Fig. 3, we demonstrate the pipeline operation of a multi-hop route based on pair-to-pair forwarding, enabled by PNC. Except at the source pair, there is no need for half-packet sharing in subsequent buddy pairs for subsequent pair-to-pair transmission. The top receiver has already demodulated a digital half-packet (labeled in figure) that can be directly used. As a result, all short hop (intra-pair) transmissions can happen simultaneously along the entire BR route, without incurring severe interference.

In contrast, Fig. 4 depicts the pipeline operation of a BR route enabled by A&F. We highlight that, in order to prepare for the pair-to-pair transmission, intra-pair sharing of a half-packet is required at each hop. This is an extra step of transmission that does not exist in the PNC-enabled BR route. As a result, an extra time slot is required for scheduling such intra-pair half-packet sharing, leading to a lower end-to-end data throughput.

B. PNC vs. A&F: One-hop BER

We first analyze the BER performance of PNC, and then compare with the BER of A&F. We ignore the BER for the Tx node to share $x_1$ with its buddy, since it is the same for both schemes, and is relatively small, due to the short distance.

1) BER of PNC: For the one-hop gadget in Fig. 2, the BER performance of PNC can be analyzed in two phases. In phase one, we study the BER at $N_1$, for decoding $x_1 + x_2$. In phase two, we study the BER at $N_2$ for decoding $x_1$ and $x_2$, assuming an adapted version of Maximum-Likelihood (ML) detection [7].

**BER at $N_1$.** $N_1$ will demodulate $x_1 + x_2$ by applying ML detection and PNC mapping. Let $c = x_1 + x_2$, which is in the $\{-2, 0, 2\}$ domain according to PNC mapping under BPSK modulation. Let $c_i$ and $c_k$ be two possible transmit vectors, with $i, k \in \{1, 2, 3\}$ being indices to $\{-2, 0, 2\}$. Assume $c_i$ is received, the probability that $N_1$ incorrectly outputs $c_k$ is:

$$P_r(c_i \rightarrow c_k) = Q\left(\frac{d_{ik}^2}{2\sigma^2_{\text{PNC-S}}A}\right) = Q\left(\sqrt{\frac{\lambda_{ik}^2 \rho_i}{2}}\right),$$
where $\lambda_k = (c_1 - c_k)^T (c_1 - c_k)$, and $p_1$ is the received SNR at N1. Function $Q$ computes the area under the tail of a Gaussian PDF.

The ternary values in $\{-2, 0, 2\}$ appear in $c$ with probabilities of: $c_1 = -2 : 25\%$, $c_2 = 0 : 50\%$, $c_3 = 2 : 25\%$, assuming 0 and 1 are equally possible to appear in the original data packet. $P_1_{c_1} - P_1_{c_3} = 0$ when both $c_1$ and $c_3$ are in $\{\pm 2, \pm 2\}^T$. In other words, judging $-2$ to be $+2$ or vice versa does not lead to an error in $x_1 + x_2$. $N1$ wishes to demodulate the digital bits $x_1 + x_2$. The average vector error probability, which is also the bit error rate, for $x_1 + x_2$ is

$$Pr_s(x_1 + x_2) = Pr_s(x_1 + x_2) = 2P_1(c_1)Pr_1(c_1 \rightarrow c_2) + P_1(c_2)\sum_{i \neq 2} Pr_1(c_2 \rightarrow c_1)$$

**BER at N2.** We apply adapted ML, a detection scheme tailored for collaborating PNC receivers recently proposed by us [7], to decode $x_1$ and $x_2$. Before applying the normal min-distance criterion in ML, it first filters out the enumerated vectors that are not in agreement with the known values for $x_1 + x_2$, to reduce the computational complexity. Using 16QAM modulation, there are 16 such vectors, with dimension $2 \times 1$. $x_1$ and $x_2$ are two distinct vectors among the sixteen. Let $\Lambda_c$ and $\Lambda_w$ denote the events that N2 receives the correct and wrong data in $x_1 + x_2$ from N1, respectively. The average vector error probability when $x_1 + x_2$ is correct is

$$Pr_s(\tilde{x}|\Lambda_w) = \frac{1}{16} \sum_{i=1}^{16} \sum_{k=1}^{16} Q\left(\sqrt{\frac{\lambda_i}{10}}\right).$$

Here $\lambda_i = (\hat{x}_i - \hat{x}_k)^T (\hat{x}_i - \hat{x}_k)$, $p_2$ is the received SNR at node 2. In the constellation graph with ML decoding, when noise exceeds the decision threshold, only 1 bit will be in error. Thus, the approximate BER can be computed as

$$Pr_s(\tilde{x}|\Lambda_w) \approx \frac{Pr_s(\tilde{x}|\Lambda_w)}{4}$$

We next analyze the case that $x_1 + x_2$ transmitted from N1 contains error. We have $Pr_s(\tilde{x}) = Pr_s(\tilde{x}|\Lambda_w)Pr_s(\Lambda_w) + Pr_s(\tilde{x}|\Lambda_c)Pr_2(x_1 + x_2)$. When information from N1 is wrong, N2 outputs a wrong vector with probability $1$, i.e., $Pr_2(\tilde{x}|\Lambda_w) = 1$. Therefore the vector error rate of the overall PNC-based scheme is

$$Pr_s(\tilde{x}) = Pr_s(\tilde{x}|\Lambda_w)(1 - Pr_2(x_1 + x_2)) + Pr_2(x_1 + x_2).$$

2) **BER of Amplify&Forward**: The analysis of BER performance for A&F with ML detection is similar to that of a basic $2 \times 2$ MIMO link. N2 can decode $x_1$ and $x_2$ after receiving the amplified signal from N1. The vector error rate of A&F is:

$$Pr_s(\tilde{x}|\Lambda_w) = \frac{1}{4} \sum_{i=1}^{4} \sum_{k=1}^{4} Q\left(\sqrt{\frac{\lambda_i}{2}}\right).$$

where $\lambda_i = (\hat{x}_i - \hat{x}_k)^T (\hat{x}_i - \hat{x}_k)$, $\hat{x}_i$ and $\hat{x}_k$ are two possible spatial source vectors and $i, k \in \{1, \ldots, 4\}$. $\rho$ is SNR at the receiver side. Then the BER of A&F can be approximated as:

$$Pr_r(\Lambda_w) \approx Pr_r(\Lambda_w)/2.$$
B. The Capacity of A BR Route

To analyze the end-to-end routing capacity of a BR route, we first compute $SNR_{short}$ and $SNR_{long}$, BER values in the short and long transmissions, respectively.

Assume the path loss factor is 3, and the distance between a wireless Tx node and Rx node is $d$. Then the power available at the receiving antenna can be expressed by the power for the transmitting antenna and distance, which is $P_r = P_t / d^3$. Considering interference from immediate neighboring pairs along the BR path, the SNR of the short hop can be approximated as:

$$SNR_{short} = \frac{P_t / d^3}{\sigma^2 + 2 \times P_t / d_1^3}$$  \hspace{1cm} (1)

Here $\sigma^2$ is the intensity of additive white Gaussian noise. Considering interference from the closest two pairs that transmit concurrently in the BR TDMA scheme, the SNR of the long hop can be approximated as:

$$SNR_{long} = \frac{2 \times P_2 / d_2^3}{\sigma^2 + 2 \times P_2 / (2d_2)^3}$$  \hspace{1cm} (2)

According to the Shannon-Hartley Theorem, the capacity of a wireless link $l$ is

$$C_l = B_l \log_2(1 + SNR_l),$$

where $C_l$ is the channel capacity in bps and $B_l$ is the bandwidth of the channel in hertz. The capacity of a $k$-hop BR route is the bottleneck capacity among all the long (inter-pair) and short (intra-pair) transmissions, at each hop $i$:

$$C_{BR} = \min\{C_{long-i}, C_{short-i}\} | 1 \leq i \leq k$$

Capacity at very high SNR. We first simulate the BR route capacity with noise ignored. Fig. 7 shows that the BR route capacity decreases when $d_1/d_2 > 0.39$. On the other hand, the ratio between $P_1$ and $P_2$ has no significant effect on the capacity. In this set of simulations, $B = 100KHz$, $P_2 = 100\mu W$, $d_2 = 50dm$.

Without background noise, with constant $P_2$ and $d_2$, inter-pair link capacity is constant and does not depend on $P_1/P_2$. When $\alpha = d_1/d_2 < 0.39$, the bottleneck of the BR route lies in the inter-pair transmissions. When $\alpha > 0.39$, the bottleneck becomes the intra-pair links, whose capacity decreases as $d_1$ increases.

Capacity with noise considered. We next simulate the capacity of a BR route with noise considered. Fig. 8 shows a decreasing trend of the BR route capacity as noise grows. In this set of simulations, noise intensity varies from $0 \times 10^{-7} W$ to $4 \times 10^{-7} W$, $P_2 = 100\mu W$, $d_2 = 50dm$, $d_1 = 5dm$. The bottleneck resides in the inter-pair transmissions, and changes in $\beta = P_1/P_2$ has no affect on capacity.

![Fig. 7. BR route capacity with different values for $P_1/P_2$ and $d_1/d_2$.](image)

![Fig. 8. Capacity with the effect of noise, $\alpha = 0.1$. BR route bottleneck exists in inter-pair transmissions, $P_1/P_2$ is irrelevant.](image)

The short hop becomes a bottleneck when $SNR_{short} < SNR_{long}$. Substituting (1) and (2) into this inequality, we obtain the equivalent condition of

$$\sigma^2 < \gamma, \text{ and } \alpha < \left(\frac{\beta}{2}\right)^{1/3}$$

or

$$\sigma^2 > \gamma, \text{ and } \alpha > \left(\frac{\beta}{2}\right)^{1/3},$$

where $\gamma = \frac{(16-\alpha^{-3})P_2}{4\alpha^{-3}}$.

For the simulations in Fig. 9, $\sigma^2$ varies from $0 \times 10^{-7} W$ to $4 \times 10^{-7} W$, $P_2 = 100\mu W$, $d_2 = 50dm$, $d_1 = 30dm$. Under such parameter settings, the bottleneck switches to the intra-pair links. Overall BR capacity decreases gradually as the noise level escalates.

![Fig. 9. Capacity with the effect of noise, $\alpha = 0.6$. BR route bottleneck exists in intra-pair links, $P_1/P_2$ is relevant.](image)
routed, the total power consumption along the entire BR route increases. We therefore face a fundamental tradeoff between capacity and energy efficiency.

C. Power Consumption: BR vs. Point-to-Point Routing

Next, we compare the energy consumption, for routing the same amount information, between Buddy Routing and traditional point-to-point schemes. Again, we assume that BPSK and 16QAM are selected for modulation in the long and short BR transmissions, respectively. For point-to-point routing, a single node relays the data packet at each hop, using BPSK modulation. Let \( t \) be the time duration for one antenna to transmit one packet with BPSK modulation, and \( k \) be the number of (long) hops from the source to the destination. At each hop, the energy consumption ratio between BR and point-to-point routing is

\[
\frac{2P_1^2}{P_2 t} + \frac{2P_1^2}{P_2 t} = 1 + \frac{P_1}{4P_2}
\]

The ratio of total energy consumption along the entire route is

\[
\frac{k(2P_1^2) + (k+1)(P_1^2)}{kP_1 t} = 1 + \frac{(k+1)P_1}{8kP_2}
\]

Fig. 10 plots the energy consumption ratio computed above, with \( P_2 = 100 \mu W, d_1 = 5 \text{dm}, \alpha = 0.1, d_2 = 50 \text{dm}; k = [2, 4, 8, 12, 30, 50, 100] \) (each corresponding to a line in the figure). The energy consumption ratio decreases when \( P_1 \) is smaller, while the value of \( k \) doesn’t have a great influence on the ratio. Overall, the extra power consumption overhead caused by BR is mostly below 20%, and further decreases to below 5% when \( P_1/P_2 < 0.5 \). Such a comprise can be well justified by the potential capacity gain of a factor of 2.

A. The BR Algorithms for Unicast

Table I presents the algorithms for BR unicast. Here \( r_b \) (radius of smallest circle in Fig. 11) is the maximum distance between a pair of buddy nodes, \( r_{\text{min}} \) (medium circle) and \( r_{\text{max}} \) (large circle) are the minimum and maximum allowed distances between two neighbor buddy pairs, respectively.

2. Iterative MAC layer optimization

\( \delta \leftarrow 1 \)

while \( \delta > \epsilon \):

2.1. adjust time slot lengths in \( t_{11}, t_{12}, t_{13} \) and \( t_2 \)

- so that the capacity in each time slot is equal

2.2. intra-pair power optimization

- adjust \( P_t \) of bottleneck long BR hop & neighbor pairs
- achieve equal capacity at bottleneck link & 2 neighbor links

2.3. intra-pair power optimization

- adjust \( P_t \) in bottleneck short BR pair & neighbor pairs
- achieve equal capacity at bottleneck pair & 2 neighbor pairs
- \( \delta \leftarrow \) increment in end-to-end capacity due to 2.1-2.3

end while

The idea behind BR unicast routing is to extend the well-known greedy geographical routing algorithm [8], which is known for its light-weight and fully distributed nature, form the point-to-point domain to the pair-to-pair domain. At each step in the iterative forwarding process, the algorithm looks for a next-hop pair between the two co-axial circles of radius \( d_3 \) and \( d_2 \), which is closest to the destination. The routing algorithm assumes a relatively dense network, such that the search for a buddy within a pair and the search for a next-hop pair of buddies can succeed. If the network density does not meet such a desired property, a hybrid route that combines pair-to-pair BR routing and traditional point-to-point routing can be resorted to.

We now take an overview of the complexity of the BR algorithms, for application in a NanoNet. The iterative power refinement is based on simple computation and neighbor communication only. The TDMA MAC is known for its low overhead, when compared to random access based protocols. The greedy geographical routing is stateless and of light weight. However, obtaining and maintaining location information at nanonodes may constitute a considerable overhead, if the NanoNet consists of mobile nodes. Our current design of BR is therefore more suitable for a relatively static network environment. Lastly, while the original proposal of PNC requires symbol level synchronization and accurate estimation of channel state information,
such requirements are relaxed in the latest developments of asynchronous physical layer network coding [12].

Fig. 11. BR unicast based on pair-to-pair greedy geographical routing.

Fig. 11 depicts a multi-hop unicast route found by the BR unicast routing algorithm. We have further enhanced the algorithm in Table I with a number of extra functionalities. First, in the case that the last pair of buddies in the BR route (excluding the destination pair) is too close to the destination, it will be discarded and replaced by a new pair with roughly equal distance to the destination and the previous pair. Second, we further implemented the planar face routing module [8] to enable the greedy geographic routing algorithm to be able to route around a large area void of wireless nodes, as shown in Fig. 12.

B. Simulation Results: BR Unicast

Fig. 13 depicts the effectiveness of the MAC optimization module in part 2 of Table I. In this set of simulations, 700 nodes are deployed in the network, each with maximum Tx power of 120μW. The end-to-end capacity of the BR route monotonically increases, and stabilizes after five rounds. The increment in each round is more or less random, and is not monotonic. End-to-end throughput is more than doubled after the iterative power/MAC optimization.

Fig. 14 compares the end-to-end throughput of BR with traditional point-to-point routing, both with and without MAC layer optimization, in networks of various sizes. The maximum power available for each node is 120μW. Each throughput is computed as the average of five executions of the routing algorithm in question, over different network topologies. We can see that throughput of buddy routing after optimization is almost twice of that of point-to-point routing. The underlying reason for such a gain is simple yet fundamental: the BR gadget in Fig. 2 has twice the capacity of a point-to-point link, under equal nodal power budget. Such a significant gain in throughput can well justify the 5% to 20% overhead in power consumption observed in Sec. III-C.

Fig. 15. BR Unicast, end-to-end throughput comparison, with varying maximum node power.

Fig. 15 shows a similar throughput comparison as in Fig. 14, with varying maximum node power instead of varying network sizes. A similar throughput gain is observed, which appears not sensitive to the choice of the maximum node power.

V. CONCLUSION

New wireless sensor networks with extremely small and power limited devices, exemplified by the NanoNet, are envisioned to play an important role in our future lives. We proposed a new routing
paradigm tailored for such type of networks, Buddy Routing. BR groups weak wireless nodes into groups for collaborative data forwarding, based on a recent technique of physical layer network coding. By paying a moderate price in energy efficiency (energy consumed in per bit end-to-end transmission), BR has a potential to break through the nodal power limit in NanoNets, substantially improving the unicast and multicast throughput, as verified by our theoretical analysis and simulation results.
