Abstract

Background and Aims: The association between HLA-DP single nucleotide polymorphisms (SNPs) and chronic hepatitis B virus (HBV) infection varies between different populations. We aimed to study the association between HLA-DP SNPs and HBV infection and disease activity in the Chinese population of Hong Kong.

Methods: We genotyped SNPs rs3077 (near HLA-DPA1) and rs9277378 and rs3128917 (both near HLA-DPB1) in 500 HBV carriers (hepatitis B surface antigen [HBsAg]-positive), 245 non-HBV infected controls (HBsAg- and antibody to hepatitis B core protein [anti-HBc]-negative), and 259 subjects with natural HBV clearance (HBsAg-negative, anti-HBc-positive). Inactive HBV carriers state was defined by HBV DNA levels <2,000 IU/ml and persistently normal alanine aminotransferase level for at least 12 months.

Results: Compared to the non-HBV infected subjects, the HBV carriers had a significantly lower frequency of the rs3077 T allele (p = 0.0040), rs9277378 A allele (p = 0.0068) and a trend for lower frequency of rs3128917 T allele (p = 0.054). These alleles were associated with an increased chance of HBV clearance (rs3077: OR = 1.41, p = 0.0083; rs9277378: OR = 1.61, p = 0.00011; rs3128917: OR = 1.54, p = 0.00017). Significant associations between HLA-DP genotypes and HBV clearance were also found under different genetic models. Haplotype TAT was associated with an increased chance of HBV clearance (OR = 1.64, p = 0.0013). No association was found between these SNPs and HBV disease activity.

Conclusion: HLA-DP SNPs rs3077, rs9277378 and rs3128917 were associated with chronicity of HBV disease in the Chinese. Further studies are required to determine whether these SNPs influence the disease endemicity in different ethnic populations.

Introduction

Approximately 400 million people worldwide are chronic carriers of hepatitis B virus (HBV) [1]. The disease spectrum of chronic hepatitis B varies among patients, ranging from inactive non-replicative to active replicative state, which may lead to fulminant hepatic failure, liver cirrhosis, or hepatocellular carcinoma (HCC). While persistence or resolution of HBV infection may be affected by a variety of factors, including viral, environmental and host factors, family or twin studies have suggested that host genetic constitution is also an important factor which influences chronicity of HBV infection [2,3]. Many host genetic variations, including genes coding for cytokines such as interferon-gamma and tumor necrosis factors [4], estrogen receptor alpha [5], vitamin D receptor [6], mannose-binding protein [7], cytotoxic T-lymphocyte antigen 4 (CTLA-4) [8] and human leukocyte antigen (HLA) [9,10,11,12], have been suggested to influence chronicity or clearance of HBV infection. In particular, single nucleotide polymorphisms (SNPs) near the CTLA-4, genes coding for an inhibitory receptor expressed by T-lymphocytes, and near the HLA-DR13 locus, coding for component of the major histocompatibility complex class II cell surface receptors, have been studied in several case-control studies for their association with HBV infection in different populations [8,9,10,11,12]. However, these candidate gene studies were not conducted on a large scale genome-wide approach.

Several genome-wide association studies (GWAS) have been performed with large cohorts to study the association of genetic
variations with HBV infection. These GWAS studies did not find a
strong association between HBV infection and those previously
identified candidate HBV-associated SNPs. These GWAS studies
demonstrated that certain SNPs near the HLA-DP loci, are
associated with persistent HBV infection [13,14,15]. In a
pioneering GWAS study with 706 Japanese chronic HBV carriers
and 2,201 controls, Kamatani and colleagues have identified an
association between chronic hepatitis B and 11 SNPs in the HLA-
DP region, two of which, namely rs3077 and rs9277355, were
further validated in three additional Japanese and Thai cohorts
[13]. The association between these HLA-DP SNPs with chronicity
and/or clearance of HBV infection was further confirmed by two
other GWAS studies, one with 2,667 Japanese chronic HBV
carriers and 6,496 controls by the same group [14] and one with
181 Japanese chronic HBV carriers, 184 healthy controls, and 185
individuals with natural clearance of HBV [15]. The association
of some of these HLA-DP SNPs with HBV infection has been verified
in many studies, but the association differs between studies in
different population cohorts, and more SNPs are yet to be
identified [16,17,18,19,20,21].

HLA-DP molecules, belonging to HLA class II, are involved in
antigen presentation to CD4+ T helper cells. As HLA-DP plays an
important role in host-immune response and particularly antigen
presentation, it would be interesting to investigate the possible
association of the HLA-DP loci variations with hepatitis B disease
activity, which is immune-mediated. Since the findings are not
consistent in different study cohorts [18,20], the association of
these HLA-DP SNPs with HBV disease activity remains unclear.

In the present study, we primarily aimed to investigate the
association of 3 HLA-DP SNPs, namely rs3077, rs9277378 and
rs3128917, with chronicity of HBV infection in the Chinese
population in Hong Kong. In addition, we studied the association
of these SNPs with hepatitis B disease activity. This will extend our
understanding of the association between HLA-DP variations and
HBV infection and may provide some evidences to explain the
widely different prevalence of chronic HBV in different ethnic
groups in the world.

Patients and Methods

Patients

The present study recruited 500 chronic HBV carriers (hepatitis B
surface antigen [HBsAg]-positive for more than 6 months) who
had been followed up in our liver clinics in the Queen Mary
Hospital, Hong Kong. Upon their first and/or follow up visits,
these HBV carriers had given verbal informed consent for the
storage of blood samples for further studies. We have also
recruited 706 consecutive HBsAg-negative control subjects who
have donated blood at the Hong Kong Red Cross Blood
Transfusion Service, and they all had given verbal informed
counsel during blood donation for the storage of blood samples.
Data were analyzed anonymously for the 706 HBsAg-negative
blood donors. Approval has been obtained from the Institution
Review Board, Queen Mary Hospital, The University of Hong
Kong, for retrieving archived samples for this study. Among the
706 HBsAg-negative subjects, 202 had previous history of hepatitis
B vaccination and were excluded from the subsequent analysis. All
study patients/subjects are Chinese, and all blood samples were
collected during the period January 2010 to March 2011. All
subjects were tested negative for hepatitis C virus and human
immunodeficiency virus by the Procleix Ultro assay (Novartis
Diagnostics, Emeryville, CA).

Of the 504 non-vaccinated control subjects, 259 had HBV
natural clearance (HBV clearance group), denoted by the presence
of detectable anti-HBc by the Elecsys assay (Roche Diagnostics,
Basel, Switzerland). The remaining 245 subjects (non-HBV
infected group) were negative for both HBsAg and anti-HBc.
Longitudinal clinical data, including alanine aminotransferase
(ALT) and HBV DNA measurements, were obtained from the 500
HBV carriers. Inactive asymptomatic HBV carriers were defined
by HBV DNA levels <2,000 IU/ml and persistently normal ALT
(<58 U/L for male and <36 U/L for female) for least 12 months.

Genotyping Assays

Three SNPs within chromosome 6, namely rs3077 (in the 3’
untranslated region of the HLA-DPA1 gene), rs9277378 and
rs3128917 (inside and near the HLA-DPB1 gene, respectively),
were studied (Figure 1). rs3077 was selected for this study because
rs3077 and rs9277355 (at the 3’ untranslated region of HLA-
DPB1) have been identified to be strongly associated with
persistent HBV infection [13]. We chose to study rs9277378
instead of rs9277535 because, our previous large scale genotypic
analysis revealed that, rs9277378 was more readily detected in
DNA extracted from sera than rs9277535 (data not shown).
Moreover, linkage disequilibrium (LD) analysis by the haplotype
software (version 4.2) revealed that rs9277378 has a strong LD
with rs9277535 (D’ = 1.00, R2 = 0.954) in the HapMap Han
Chinese in Beijing (CHB) and Japanese in Tokyo (JPT)
populations. [22] We also confirmed, in a small subset of 50
randomly selected samples from the current study, that rs9277355
and rs927738 genotypes were concordant in 48 (96%) samples
with a strong LD (D’ = 1.00, R2 = 0.903). The SNP rs3128917 was
also chosen for the present study, as this SNP has the highest odds
ratio (OR) among 11 SNPs which influence chronicity of HBV
infection [16].

The 3 selected SNPs, rs3077, rs9277378 and rs3128917, were
genotyped using the TaqMan SNP genotyping assay (Life
Technologies, Carlsbad, CA). Briefly, free circulating DNA was
extracted from 200 μl of serum samples, using the Purelink
Genomic DNA Mini Kit (Life Technologies). The SNP genotyp-
ing reaction was performed in a TaqMan real-time PCR format,
using SNP-specific primers and FAM- and VIC-labeled allele-
specific probes provided in the TaqMan SNP genotyping kit (Life
Technologies) and the real-time PCR enzymes and reagents
provided in Quantifast Probe PCR Kit (QIAGEN, Hilden,
Germany). The real-time PCR reaction was performed in a
RotorGene-Q real-time PCR System (QIAGEN).

Statistical Analyses

Statistical analyses were performed using PLINK v.1.07
(http://pngu.mgh.harvard.edu/purcell/plink/) [23] and SPSS
18.0 (SPSS Inc., Chicago, IL). Logistic regression was performed
to compare between case and control groups, and all ORs and p
values were adjusted for age and sex. The Student t test was used
to test normally distributed variables. Categorical variables were
tested by the Chi-square test. Statistical significance was defined
by p<0.05.

Results

Demographic Characteristics and Hardy-Weinberg
Equilibrium

The mean age of the HBV carriers was 46.8±12.1 years, which
was significantly higher than that of the non-HBV infected
subjects (36.4±9.9 years; p<0.0001) and that of the HBV
clearance subjects (40.3±10.9 years; p<0.0001). The proportion
of male (304/500; 61%) in the HBV carriers was significantly
higher than that in the non-HBV infected group (127/245; 52%
Figure 1. Relative locations of the three studied SNPs and HLA-DPA1 and HLA-DB1 genes on chromosome 6. The names of the three SNPs are shown on top, and the chromosomal positions on chromosome 6 are marked in the ruler in the middle. The HLA-DPA1 and HLA-DB1 genes are shown as arrows in the bottom, with the exons shown as black boxes, introns as white boxes, and un-translated regions as gray boxes/arrows.

doi:10.1371/journal.pone.0066920.g001

p = 0.020), but did not differ from that in the HBV clearance subjects (152/259; 59%; p = 0.573). Three SNPs (rs3077, rs9277378, and rs3128917) were genotyped in these 500 HBV carriers, 245 non-HBV infected controls and 259 HBV clearance subjects. All 3 polymorphisms in the HBV carriers, non-HBV infected controls and HBV clearance subjects were in Hardy-Weinberg equilibrium, and there was no significant difference between the observed and expected genotypic frequencies in all 3 SNPs in all 3 groups (all p > 0.05; Table S1).

Association between HLA-DP Polymorphisms and Chronicity of HBV Infection

The allelic frequencies of the three studied SNPs are listed in Table 1. The minor alleles for rs3077, rs9277378 and rs3128917 determined from the present study cohort were T, A and T, respectively. There was a significantly higher proportion of the rs3077 and rs9277378 minor alleles (T and A, respectively) in the non-HBV infected controls than in the HBV carriers (p = 0.0040 and 0.0068, respectively). There was a trend of a higher proportion of the rs3128917 T allele in the non-HBV infected controls than in the HBV carriers (p = 0.054). The HBBV clearance subjects had a significantly higher proportion of rs3077 T allele, rs9277378 A allele, and rs3128917 T allele than in the HBV carriers (p = 0.0083, 0.0011, and 0.00017 for rs3077, rs9277378 and rs3128917, respectively).

Genotype frequencies for the 3 SNPs were compared between the HBV carriers and non-HBV infected controls, as well as between the HBV carriers and HBV clearance group. The genotype distributions of the 3 study groups are listed in Table 2. Compared with the non-HBV infected controls, HBV carriers had a lower prevalence of the minor alleles of rs3077 and rs9277378, as shown by both the dominant-effect (homozygote minor allele vs. homozygote major) model (p = 0.0089 and 0.0162 for rs3077 and rs9277378, respectively) and the additive-effect (additive dosage of minor allele) model (p = 0.0036 and 0.0058 for rs3077 and rs9277378, respectively). There was also a lower frequency of the rs3128917 T allele in the HBV carriers when analyzed using the dominant-effect model (p = 0.0395), but the difference was only marginal when the additive-effect model was applied (p = 0.0561).

Comparison was also made between the HBV carriers and HBV clearance subjects to test the association of these 3 SNPs with natural clearance of HBV infection. As shown in Table 2, rs3077 T allele, rs9277378 A allele, and rs3128917 T allele were associated with an increased chance of clearance of infection in both the dominant-effect model (rs3077: OR = 1.42, 95% confidence interval [CI] = 1.04–1.95, p = 0.0284; rs9277378: OR = 1.61, 95% CI = 1.18–2.2, p = 0.0029; and rs3128917: OR = 1.79, 95% CI = 1.29–2.48, p = 0.00054) and the additive-effect model (rs3077: OR = 1.42, 95% CI = 1.18–1.83, p = 0.0079; rs9277378: OR = 1.62 95% CI = 1.27–2.07, p = 0.00011; and rs3128917: OR = 1.52, 95% CI = 1.22–1.9, p = 0.00024).

Genotypic analysis showed that rs9277378 AA genotype might be most relevant to the clearance of HBV infection (OR = 3.20, p = 8.71 × 10⁻⁵; Table 2). Therefore we performed subgroup analysis to investigate the role of rs3077 and rs3128917 in the patients/subjects with rs9277378 GG genotype, which represent the genotype least likely to clear HBV infection. As shown in Table 2, 398 patients/subjects had rs9277378 GG genotype: 283 (56.6%) HBV carriers and 115 (44.4%) subjects with HBV clearance. Among these 398 patients/subjects, there was no significant difference between the HBV carriers and HBV clearance subjects in the proportion of the protective allele of rs3077 and rs9277378, respectively (additive dosage of minor allele) model (p = 0.0089 and 0.0162 for rs3077 and rs9277378, respectively) and the additive-effect (additive dosage of minor allele) model (p = 0.0036 and 0.0058 for rs3077 and rs9277378, respectively). There was also a lower frequency of the rs3128917 T allele in the HBV carriers when analyzed using the dominant-effect model (p = 0.0395), but the difference was only marginal when the additive-effect model was applied (p = 0.0561).

Comparison was also made between the HBV carriers and HBV clearance subjects to test the association of these 3 SNPs with natural clearance of HBV infection. As shown in Table 2, rs3077 T allele, rs9277378 A allele, and rs3128917 T allele were associated with an increased chance of clearance of infection in both the dominant-effect model (rs3077: OR = 1.42, 95% confidence interval [CI] = 1.04–1.95, p = 0.0284; rs9277378: OR = 1.61, 95% CI = 1.18–2.2, p = 0.0029; and rs3128917: OR = 1.79, 95% CI = 1.29–2.48, p = 0.00054) and the additive-effect model (rs3077: OR = 1.42, 95% CI = 1.18–1.83, p = 0.0079; rs9277378: OR = 1.62 95% CI = 1.27–2.07, p = 0.00011; and rs3128917: OR = 1.52, 95% CI = 1.22–1.9, p = 0.00024).

Genotypic analysis showed that rs9277378 AA genotype might be most relevant to the clearance of HBV infection (OR = 3.20, p = 8.71 × 10⁻⁵; Table 2). Therefore we performed subgroup analysis to investigate the role of rs3077 and rs3128917 in the patients/subjects with rs9277378 GG genotype, which represent the genotype least likely to clear HBV infection. As shown in Table 2, 398 patients/subjects had rs9277378 GG genotype: 283 (56.6%) HBV carriers and 115 (44.4%) subjects with HBV clearance. Among these 398 patients/subjects, there was no significant difference between the HBV carriers and HBV clearance subjects in the proportion of the protective allele of rs3077 (A allele proportion = 9.2% vs. 11.3%, respectively; Table 1. Allelic difference and its association with chronicity and clearance of HBV infection.

*HBV carriers vs. non-HBV infected subjects.

†HBV clearance subjects vs. HBV carriers.

doi:10.1371/journal.pone.0066920.t002
Hepatitis B as well as viral clearance [13,14,15]. In the present study, we have studied 3 SNPs to extend our understanding of the association of these variations with HBV infection in Chinese population in Hong Kong and identified that the rs3077 T allele, rs9277378 A allele and rs3128917 T allele were protective for chronicity of HBV infection. While other studies have demonstrated that HLA-DP SNPs rs3077 and rs9277535 are strongly associated with chronic hepatitis B infection [13,14,15,16,17,18,19,20,21], to our knowledge, the present study is the first study to determine the association between rs9277378 and chronicity of HBV infection. Although it is possible that the authentic effect of rs9277378 polymorphism may be due to its high LD with rs9277535, our findings with rs9277378 suggested that more SNPs (or combination of SNPs) in the HLA-DP regions may be associated with HBV infection.

Data on the association of HLA-DP variations with chronic HBV infection are relatively scarce. In one study with 201 Caucasian chronic HBV carriers and 235 controls, the rs3077 T allele has also been identified to be protective against chronic HBV infection [18]. However, in that study, the rs3077 T protective allele was the major allele in the Caucasian cohort. This is consistent with the data from the HapMap project, which show that the frequencies of the protective alleles for rs3077 (T), rs9277378 (A) and rs3128917 (T) were higher in people with European ancestry than in the African and Asian populations [22]. Taken together, all these findings of HLA-DP genomic variations may shed light on the difference in the geographic distribution of HBV infection: it is possible that the lower prevalence of chronic HBV infection in the European/Caucasian populations is due to the higher prevalence of the protective HLA-DP alleles. Similarly, the high prevalence of chronic HBV infection in the Asian/African populations is likely due to the lower prevalence of the protective HLA-DP alleles. However, it should be noted that other factors, apart from HLA-DP variations, are also associated with chronicity of HBV infection. If the HLA-DP variations were the sole decisive factors for chronicity, the prevalence of chronic hepatitis B would have been much more than 10% in the Chinese. Moreover, a certain proportion of Asian/Chinese who possess the protective alleles may not have contacted HBV in their life time. Thus, many other factors, such as viral, environmental and other host genetic factors, are likely to be associated with chronicity of HBV infection. Nevertheless, the findings from the present as well as other genetic association studies, suggest that HLA-DP variations are probably one of the genetic factors which plays an important role in the development of chronicity of HBV infection. Clearance of HBV infection is associated with a high level of CD4+ T cells response [24,25]. HLA-DP molecules, belonging to

HLA class II, are involved in antigen presentation to CD4+ T helper cells. The antigen-binding sites of HLA-DP molecules are highly polymorphic, and they play an important role in the physical binding of peptides and subsequent recognition by T-cell [26,27]. While it can be expected that variations in the HLA-DP coding regions will affect antigen presentation and hence viral clearance, the 3 studied SNPs do not lie within the HLA-DP coding region. The SNP rs3077 lies in the 3’ untranslated region of HLA-DPA1, rs9277378 lies in the second intron of HLA-DPB1, and rs3128917 is located ∼2.5kb downstream of HLA-DPB1 (Figure 1). As variations in these SNPs will not cause specific changes in the HLA-DP coding sequence, the effect of variations in these 3 SNPs on HLA-DP function and viral clearance is likely to be indirect. There are at least two possible mechanisms. Firstly, it is possible that variation in these SNPs may alter the expression of the HLA-DP genes, through the alternation of non-coding RNA sequence or microRNA binding site, as demonstrated in a recent study that variations in rs3077/rs3128917 and rs9277353 affect the expression of HLA-DPA1 and HLA-DPB1 respectively [28]. Secondly, as these SNPs are in a strong LD with the HLA-DP alleles, it is also likely that variations in these 3 SNPs reflect some yet to be identified variations in HLA-DP coding sequence [13,16]. Thus variations in these 3 SNPs may be a marker for the variations in the HLA-DP coding sequence, which in turn affect antigen presentation of HBV-derived peptides and alter immune response and chronicity of infection. In fact, it has been demonstrated in a chimpanzee HBV infection model that the outcome of HBV infection is determined by the kinetics of viral spread and CD4 T-cell priming [29]. This suggests that the outcome of HBV infection can be influenced by the physical binding of HBV-derived peptides and their subsequent recognition by CD4 T-cell, which is dependent on HLA-DP polymorphism. The correlation between variations in HLA-DPA1 and HLA-DPB1 SNPs and the change in HLA-DP gene expression and molecule structure deserves a more thorough sequence analysis, and the functional roles of these polymorphisms remain to be studied.

Haplotype-based association analysis is more sensitive than individual SNP association analysis and can capture additional phenotype-related variants with a greater statistical power. This study found that both haplotypes TAT and CAT were associated with an increase chance of HBV clearance, with ORs of 1.64 and 1.96, respectively, both of which were greater than that of the individual SNPs (Table 1). However, there are two caveats. First, although the haplotype CAT showed the greatest OR of 1.96, its relatively greater 95% CI range and low overall haplotype frequency (0.097; data not shown) suggested that its effect on HBV clearance requires further investigations. Second, compared to the OR for individual alleles in the SNPs (for example, for rs9277378, OR = 1.61; Table 1), there was only a small increase in OR by the current haplotype analysis. In this current study, we found that the rs9277378 AA genotype might have the strongest association with HBV clearance (Table 2), and subgroup analysis indicated that the role of other protective SNPs in the rs9277378 GG subgroup was not significant. Therefore individual SNP analysis may be sufficient to provide information on the single most relevant and best-associated SNP with HBV clearance. Nevertheless, haplotype analysis may still have its value by increasing the statistical power in the association analysis and taking into account the effect of variants in other SNPs. Given the greater genetic distance and weak LD between rs3077 (near HLA-DPA1) and the two other SNPs (rs9277378 and rs3128917; both near HLA-DPB1) and the relatively high LD between rs9277378 and rs3128917 (Table S2), it is possible that the two HLA-DPB1 SNPs form an haplotype block while rs3077 belongs to a distinct haplotype block. Our finding that haplotype of the HLA-DPB1 SNPs (rs9277378 and rs3128917) alone was associated with HBV clearance (OR = 1.70), independent on the effect of HLA-DPA1 SNP rs3077, also pointed to this possibility. Although, in our present analysis, the effect of rs3077 alone on HBV clearance appeared to be less than that of the rs9277378-rs3128917 haplotype, it is likely that a more complex network or combination of more SNPs in the HLA region is associated with chronicity of HBV infection. Other recent studies have identified some SNPs in the HLA-DQ region which are also associated with susceptibility to HBV infection [14,17]. The interaction between SNPs in the HLA-DP and HLA-DQ regions, their association with HBV infection in different populations, and their correlation with HLA-DP and HLA-DQ gene expression remain to be a challenging task to decode the genetic factors involved in HBV infection.

Another important finding from the present study is that we were not able to identify any association between HLA-DP genomic variations and HBV disease activity. This is consistent to other studies which also fail to identify any association between other SNPs in the HLA-DP region and HBV disease progression [18,20]. Because only a limited number of SNPs was studied in our and other studies, more in-depth studies may be required to elucidate the association between HLA-DP variations and HBV disease activity. Similarly, the association between SNPs in the HLA regions and HCC development remains to be confirmed in different study cohorts. Two recent studies had identified 3 SNPs, rs2656718 (HLA-DQA1/DQB1), rs3077 (HLA-DPA1), and rs9272105 (HLA-DQA1/DRB1) to be associated with HBV-related HCC development [17,30], while other studies failed to associate rs3077 and other HLA SNPs with HBV-related HCC development [15,21,31]. Detailed studies in different populations are needed to further elucidate the association between HLA genetic variations and HBV disease activity and HCC development.

In conclusion, we showed that HLA-DP SNP rs3077, rs9277378, and rs3120917 were individually associated with chronicity of HBV infection. Haplotype analysis revealed that haplotype TAT was strongly associated with HBV clearance. None of these 3 SNPs was associated with HBV disease activity.
