Impact of melamine-tainted milk on foetal kidneys and disease development later in life

Key Messages
1. Melamine has very low cytotoxicity on kidney cells of a susceptible species (canine), and the presence of its main degradation product cyanuric acid did not influence its cytotoxicity. This indicates that the toxicity of melamine is mainly due to the formation of kidney stones rather than a direct toxic effect on kidney cells.

2. Ingestion of melamine alone failed to induce kidney stones even under conditions of restricted drinking water access. In mice administrated with melamine together with cyanuric acid, no renal stones were formed when the supply of drinking water was unrestricted. However, when drinking water was limited, stone formation was observed.

3. Melamine was detected in the foetal circulation of perfused human placenta and easily transferred through it. The presence of cyanuric acid did not influence the transfer of melamine from the maternal to the foetal side.

4. Administration of melamine and cyanuric acid to pregnant mice did not cause any noticeable developmental or reproductive abnormalities.

5. No melamine crystals were detected in kidneys of the embryos or breastfed pubs, despite the mothers having melamine crystals in their kidneys and renal failure.

Introduction
Consumption of melamine-tainted milk products has affected tens of thousands of Chinese children. Up to 27 November 2008, 294 000 children were reported to show urinary system abnormalities, of whom 51 900 were hospitalised. It is uncertain whether such children will incur other complications such as tumourigenesis or growth retardation in the future.

Due to immaturity and quickly developing organs, foetuses may be highly susceptible to the effects of environmental toxins. There is association between growth and health of the foetus and infant and the risk of several diseases later in life. Transplacental transfer of toxic compounds via the human placenta is important for foetal risk assessment. Studies on human placenta are crucial because of functional differences in placental anatomy and physiology between different species.

In China, infant milk formula contaminated with melamine and cyanuric acid (CA) was taken by the children. These compounds have been found in food products (milk and other dairy products, eggs, chicken) that were consumed in high amounts. There is potential toxicity from consuming melamine in combination with its degradation products. This study aimed to investigate the impact of possible synergistic effects between melamine and CA and the potential of transplacental passage of melamine and its consequences on foetuses and disease development later in life.

Methods
This study was conducted from April 2009 to December 2011 and was divided into four parts to study: (1) interactive cytotoxicity of melamine and CA using Madin-Darby canine kidney cells, (2) induction of renal inflammation and kidney stones in vivo in mice, (3) the maternal foetal transplacental passage using an...
ex vivo human placenta perfusion model, and (4) short and long-term implications of exposure to melamine and CA in utero and during early stages of life in a mice model.

**Results**

**Study I: interactive toxicity of melamine and its degradation product in a cell culture model**
When melamine was mixed with CA in different ratios of 1:1, 10:1, 100:1, and 1000:1, and then incubated with Madin-Darby canine kidney cells for 48 hours, there was a very weak cytotoxic effect (as measured by the cell viability); less than 20% of the cells were adversely affected. The data obtained from the cytotoxicity assays of melamine and CA was compared with the effect of melamine and CA alone (Fig 1).

**Study II: induction of renal inflammation and kidney stones in vivo in mice**
In mice, ingestion of melamine alone failed to induce kidney stones. However, when melamine was co-administered with CA in different ratios, renal inflammation and the formation of kidney stones were observed (Fig 2).
El-Nezami et al

stones even under conditions of restricted drinking water. When melamine was administrated with cyanuric acid for 3 days, no renal stones were formed when drinking water was unrestricted, but when drinking water was limited, stone formation accompanied by high levels of serum urea and creatinine were observed (Fig 2).

**Study III: maternal foetal transplacental passage using an ex vivo human placenta model**

When placentas were perfused with 10 μM melamine, approximately 0.15% of that concentration was detected in the foetal circulation after 5 minutes. The amount of melamine increased in the foetal circulation and decreased in the maternal circulation over time and at the end of the 4-hours perfusions, a mean of 62% and 39% of the original melamine concentration were detected in the maternal and foetal circulation, respectively.

As a rat study indicated that melamine transfer through placenta is dose dependent, additional perfusion experiments with 1 mM melamine were carried out to investigate whether there was a difference in the transfer based on concentrations. Transfer of 1 mM melamine did not differ significantly.

Because melamine contaminated products may contain CA, perfusions were carried out with a mixture of 10 μM melamine with 10 nM of CA, to investigate whether CA affected the transfer of melamine. Transfer of melamine in these perfusions was similar, irrespective of the CA concentrations.

**Study IV: short- and long-term implications of exposure to melamine**

There were no significant changes in the number of mouse embryos in the control and melamine mothers. However, embryos in the latter mothers were slightly smaller in size. Morphological and histological examination of the embryos revealed no obvious bleeding or other abnormalities, and the blood vessels were well developed (Fig 3).

**Discussion**

Although the pathophysiology of urinary stones secondary to exposure to both melamine and CA has been reported, their combined action on kidney cells remains unknown. Study I screened for interactive toxicity of melamine and CA using a cell culture model. No additive or synergistic interactions were noted when mixed in ratios of 1:1, 10:1, 100:1, and 1000:1. Melamine generally appeared to reduce the harmful acidic effects induced by CA.

The effects of melamine and CA uptake on kidney stone formation have been reported in fish, cats, dogs, and pigs, but not in mice. Results from study II and others indicated that melamine administration alone without CA cannot induce the renal stone formation in experimental animals. When melamine and CA were administered together for 3 days, melamine crystals were found in the kidneys together with acute renal failure. However, this only occurred when access to drinking water was limited. Under conditions of unrestricted drinking water, ad libitum crystals were found very occasionally, and no dilated tubules were observed in

![Fig 2. Histology analysis of melamine stone formation in the kidney in frozen section stained with H&E: (a) frozen sections of the kidney and liver from mice fed with melamine and cyanuric acid (CA) under restricted access to drinking water (Restricted H₂O + melamine + CA) were compared to water delivered ad libitum (Unrestricted H₂O). (b) Paraffin sections of mouse kidneys under restricted access to drinking water were compared to unrestricted drinking water controls. From left to right, cortical regions of Unrestricted H₂O group and the glomeruli, tubules and medullary regions of the Restricted H₂O + melamine + CA group. Scale bar represents 50 μm. Melamine stones are indicated with arrows](image)
tissue sections and the mice had no symptoms of kidney failure. The half life of melamine in the blood is about 2.7 hours and it is cleared mainly through renal system. After restricting drinking water, melamine and CA were retained longer with higher concentrations in the kidney, enabling the two chemicals to interact and form crystals. In addition, the reduction of kidney function by crystals further limited the water exchange and the kidney failure occurred rapidly. Our results partially explained how melamine stones cause acute kidney failure in patients and animal studies.

During pregnancy, the placenta develops and its thickness and cell layers decrease from >50 μm at the 2nd month to <5 μm at the 37th week of pregnancy. Due to the changes in placenta, transplacental transfer probably varies during the course of pregnancy and because it is thinnest at term, drug transport may also be highest. Study III is the first report on melamine transfer on human placental perfusion and provides the evidence of a fast transfer through the term human placenta. Melamine crossed the placental barrier quickly, as indicated by the presence of small concentrations (0.12 to 1.34%) in the foetal circulation 5 minutes after the addition to the maternal circulation; concentrations exceeded 34% after 4 hours of perfusion. One study on the transfer and accumulation of melamine in rat foetuses and placentas suggested that the transfer of melamine is dose dependent. In our study, there was some indication of slightly quicker transfer with higher concentrations, but the difference was not significant. The kinetics of melamine clearly differed from those of antipyrine, which diffuses passively through the placenta. Transfer of melamine was significantly slower, implicating the involvement of other contributing factors such as the presence of placental efflux transporters.

Results from study IV using mouse and alternative water supply to investigate the effect of melamine and CA on embryo development suggested that stones might only be formed in a functioning kidney. As embryonic kidney has no function, hence no stone was detected in embryos from pregnant mice exposed to melamine and CA.

Acknowledgements

This study was supported as part of the Studies Related to Melamine Incident commissioned by the Food and Health Bureau, Hong Kong SAR Government (MI-BS-16). We thank Pro Kirsi Vahakangs, Prof Seppo Auriola from the School of Medicine, University of Eastern Finland, Prof Seppo Heinonen and staff of the maternity ward in Kuopio University hospital for the placental perfusion studies.
