Received May 26, 2015, and in revised form Sep 29, 2015. Accepted for publication Nov 4, 2015.

Summary
Pilocarpine has been used in the treatment of xerostomia; however, it is still uncertain whether it has a preventive effect on radiation-induced xerostomia. Our systematic review and meta-analysis demonstrated that concomitant administration of pilocarpine during radiation could increase unstimulated salivary flow rate and reduce clinician-rated xerostomia grade. It may also relieve patients’ xerostomia at 6 months, and possibly at

Purpose: To evaluate the efficacy of concomitant administration of pilocarpine on radiation-induced xerostomia in patients with head and neck cancers.

Methods and Materials: The PubMed, Web of Science, Cochrane Library, and Clinical Trials were searched to identify randomized, controlled trials studying the effect of concomitant administration of pilocarpine for radiation-induced xerostomia. Included trials were systematically reviewed, and quantifiable outcomes were pooled for meta-analysis. Outcomes of interest included salivary flow, clinician-rated xerostomia grade, patient-reported xerostomia scoring, quality of life, and adverse effects.

Results: Six prospective, randomized, controlled trials in 8 articles were included in this systematic review. The total number of patients was 369 in the pilocarpine group and 367 in the control group. Concomitant administration of pilocarpine during radiation could increase the unstimulated salivary flow rate in a period of 3-6 months after treatment, and also reduce the clinician-rated xerostomia grade. Patient-reported xerostomia was not significantly impacted by pilocarpine in the initial 3 months but was superior at 6 month. No significant difference of stimulated salivary flow rate could be confirmed between the 2 arms. Adverse effects of pilocarpine were mild and tolerable.

Conclusions: The concomitant administration of pilocarpine during radiation increases unstimulated salivary flow rate and reduces clinician-rated xerostomia grade.

12 months. However, it had no effects on stimulated salivary flow rate.

Introduction

Radiation therapy plays an important role in the multidisciplinary therapy of head and neck cancer, either as an adjunctive method or as the main treatment regimen. Among the acute and chronic side effects of radiation therapy, xerostomia is one of the most common complaints. Xerostomia is the subjective dryness of mouth, which may be associated with reduced salivary flow or changes in the composition of saliva (1, 2). Individuals with xerostomia often complain of difficulties in speech and swallowing, impairment of taste, and deterioration of dental hygiene, greatly impairing patients’ quality of life (QoL) (3).

Some treatment options have been put forward to relieve radiation-induced xerostomia, including salivary substitutes and sialagogic agents (4). Pilocarpine, a cholinergic agonist, stimulates saliva production and has been approved by the US Food and Drug Administration for the treatment of xerostomia. Preventive regimens are more promising, including submandibular gland transfer before radiation therapy, and parotid gland sparing techniques with 3-dimensional conformal or intensity modulated radiation therapy (IMRT) (5, 6). However, only selected candidates are suitable for submandibular gland transfer.

Studies have confirmed the significant role of IMRT in preventing xerostomia and maintaining normal oral functions (7-11). Even with IMRT, however, the salivary glands may still overlap the planning target volume partially, resulting in some degree of salivary gland impairment and xerostomia (8, 12, 13).

An early clinical trial revealed that the concomitant administration of pilocarpine during radiation therapy was effective in preventing radiation-induced xerostomia in patients with head and neck cancers (14). However, its exact efficacy is under investigation, and to date, no reported trial has been convincing enough to validate the efficacy of pilocarpine for the prevention of xerostomia. Compelling evidence is needed before concomitant pilocarpine can be recommended for routine use. Therefore, we aimed to conduct a systematic review and meta-analysis to evaluate the efficacy of concomitant administration of pilocarpine on radiation-induced xerostomia in patients with head and neck cancers.

Methods and Materials

Search strategy

We performed a comprehensive search in PubMed, Web of Science, Cochrane Library, and ClinicalTrials for relevant articles using different combinations of the following key words: “pilocarpine” or “salagen” and “radiation” or “radiotherapy” and “xerostomia” or “dry mouth” or “hyposalivation.” All articles published up to September 1, 2014 were reviewed in the initial stage, without any other limitations on the publication type and language. We also hand-searched the reference lists of eligible studies and relevant conference abstracts. This process was repeated until no additional studies were found.

Selection criteria

Two authors independently reviewed and selected articles according to the following inclusion criteria: (1) Included studies should be randomized controlled trials. (2) Eligible patients were diagnosed with head and neck cancers, and underwent radiation therapy as primary or adjuvant therapy. (3) Patients took pilocarpine daily during radiation therapy. (4) Patients in the control group received placebo, or no intervention for xerostomia prevention. (5) The sample size of patients receiving pilocarpine should be larger than 10.

Data extraction

Two authors independently reviewed the included articles and extracted data using a pre-established form, covering information about author, publication year, study design, country, sample size, tumor sites, exposed volume of salivary glands, intervention regimen, major endpoints, and duration of observation. The completed forms were checked by a third author. Any inconsistency was resolved through discussion and consensus.

Assessment of risk of bias in included studies

The Cochrane Collaboration’s tool (Cochrane Handbook version 5.1.0) for assessing risk of bias in randomized trials was adopted in this systematic review (15). Two authors independently evaluated the risk of bias of included trials in 6 domains. We also contacted corresponding authors for further clarity of randomization, concealment, blinding method, and incomplete outcome data. If available information was insufficient to eliminate a bias, we would define it as “unclear risk” rather than “low risk.”

Data analysis

Outcome variables were extracted for meta-analysis. For salivary flow rates, clinician-rated xerostomia grades, and patient-reported xerostomia scores, we calculated mean
was conducted in multiple centers in the United Kingdom) and SPSS Statistics (version 5.3; Oxford, United Kingdom) and SPSS Statistics (version 22.0) (SPSS, Chicago, IL).

### Results

#### Selection of trials

Of 495 reports initially identified (Fig. 1), 471 were excluded by title and abstract. The remaining 24 reports were screened at full-text level. Relevant references were manually searched, and 2 additional reports were added. According to the predefined inclusion and exclusion criteria, 8 reports of 6 clinical trials were included (18-26) (Table 1).

#### Description of the included studies and data analysis

All 6 trials in 8 articles were prospective trials. The trial by Fisher et al (19) was conducted in multiple centers in the United States, and the trial by Burlage et al (18) was conducted in 2 medical centers in the Netherlands, whereas the other included trials were single-centered.

The total number of patients was 369 in the pilocarpine group, and 367 in the control group. The mean age of patients was approximately 60 years in 5 trials (18-20, 22-26). However, in the trial by Haddad et al (21), the mean age of patients was 43 years, possibly owing to its different composition of tumors; most (76.9%) were nasopharyngeal carcinomas. The subtypes of tumors were reported according to their sites in every trial. The oropharynx, the oral cavity, and the larynx were the most commonly involved tumor sites, respectively accounting for 33.6%, 20.3%, and 19.5% (18-21, 23-26). More than 50% of the bilateral parotid glands received a dose of 50 Gy in most of the trials. An exception was the trial by Burlage et al (18): to study the influence of different exposed volumes of parotid glands, they recruited patients with a range of parotid volumes and divided them into 3 groups, which had an irradiated volume of parotid gland of 25%-45%, 46%-75%, and >75%, respectively.

A dose of 5 mg pilocarpine per administration was consistent in all the studies. Patients were instructed to take pilocarpine either 3 times daily, or 4 times. Patients took pilocarpine during radiation therapy and continued for different periods ranging from 2 weeks to 3 months. The period of follow-up varied from 5 weeks to 1 year after treatment (20, 22).

Studied endpoints included objective, clinician-rated, and patient-reported indicators evaluating the alleviation of radiation-induced xerostomia. Objective data could be the saliva flow rate calculated as mL/min, including stimulated and unstimulated salivary flow rates. Clinician-rated grades of xerostomia according to the known scales were reviewed, such as the Late Effects of Normal Tissues Subjective Objective, Management, and Analytic (LENT SOMA) scale, and the Radiation Therapy Oncology Group Acute Xerostomia Toxicity scale (27-29). Patient-reported xerostomia was measured using a visual analogue scale or Likert scale when responding to xerostomia-related

![Fig. 1. Selection process for studies included in the systematic review. Abbreviation: RT = radiation therapy.](image-url)
questions, such as the 1-item questionnaire by Gornitsky in 2004, the 6-item questionnaire by Johnson in 1993, and the 12-item questionnaire by Burlage in 2008. Because these questionnaires all focused on xerostomia and the aspects evaluated were similar, we extracted mean patient-reported scores, representing the overall xerostomia, at each time point. The scores were standardized on a 0-100 scale for final synthesis (32).

The impact of xerostomia on patients’ QoL was evaluated through validated questionnaires, such as the McMaster University Head and Neck Questionnaire, and the University of Washington-Quality of Life Questionnaire. Finally, adverse effects of pilocarpine were qualitatively assessed by reviewing records in the included clinical trials. Studies containing one or more of the above endpoints were included and thoroughly reviewed.

Risk of bias in included studies

The 6 included studies were all prospective, randomized clinical trials. It was difficult to gain information regarding allocation concealment and eliminate the risk of selection bias. In the trial by Fisher et al (19), eligible patients from multiple centers were registered to a treatment arm by Radiation Therapy Oncology Group headquarters, and patient factors were balanced by the headquarters other than by institutions. Most of the other studies, though, neglected to describe their methods of performing allocation. Considering performance bias, in the trial by Nyarady et al (23), the control group received neither pilocarpine nor placebo, so double-blinding was violated. Unclear information about the number of early dropouts was considered to be bias-producing. Intention-to-treat analysis was regarded as an ideal statistical method in such circumstances. In the study by Gornitsky et al (20), a missing data replacement technique was used, using mean values from corresponding groups. In the study by Fisher et al (19) the schedule for data collection of the University of Washington Quality of Life Questionnaire at the completion of radiation therapy was not carried out (Fig. 2).

Efficacy and safety of concomitant pilocarpine for radiation-induced xerostomia

Salivary flow rate

Three included studies measured unstimulated salivary flow rate. Their data at each time point were synthesized to calculate the MDs between groups. At baseline the

unstimulated salivary flow rates were similar between the pilocarpine and control groups (MD $-0.02\text{ mL/min}; 95\% \text{ CI } -0.13, 0.09; P = .68$). During radiation therapy the concomitant administration of pilocarpine increased the amount of unstimulated saliva per minute. Immediately after radiation therapy the unstimulated salivary flow rate of the pilocarpine group was significantly increased (MD $0.28\text{ mL/min}; 95\% \text{ CI } 0.18, 0.37; P < .00001$). The disadvantageous effect of pilocarpine continued for 3 months after radiation therapy; however, the increased rates declined over time. At 5-6 weeks the increase of unstimulated saliva increased in the pilocarpine group, no improvement in QoL during the follow-up 6 months was reported (19, 25).

A significant decrease in stimulated salivary flow rate after radiation therapy was observed in 2 trials. However, no significant difference was detected between arms (18, 20, 25).

**Clinician-rated scoring of xerostomia**

Two included studies measured the xerostomia grade using the LENT SOMA scale. Available data were synthesized at 6 months. The severity of xerostomia was less in the pilocarpine group (MD $-0.41$ points; 95% CI $-0.65, -0.17; P = .0008$) (Fig. 4).

**Patient-reported scoring of xerostomia**

Four included studies provided patient-reported xerostomia scores. Xerostomia was complained of during radiation therapy and persisted in the following 12 months. At baseline, xerostomia scores were similar between the pilocarpine and control groups (MD $-0.46; 95\% \text{ CI } -4.76, 3.84; P = .83$). After radiation therapy, patients in the pilocarpine group did feel a little better than those in the control group (MD $-9.40; 95\% \text{ CI } -17.96, -0.83; P = .03$). However, at 1-3 months after radiation therapy, patients’ scorings of xerostomia were not significantly different. Thereafter at 6 months, the xerostomia scores in the pilocarpine group were better than those in the control group (MD $-7.59; 95\% \text{ CI } -14.49, -0.69; P = .03$). At 12 months we included only 1 trial, by Burlage et al (18), indicating the favorable effect of pilocarpine (MD $-16.50; 95\% \text{ CI } -29.07, -3.93; P = .01$) (8, 13) (Fig. 5).

**Quality of life**

Two trials adopted validated questionnaires to assess QoL. XXXX et al used the McMaster University Head and Neck Questionnaire, revealing no difference between the pilocarpine and the placebo groups during or after radiation therapy. The QoL declined significantly during radiation therapy but gradually returned to the baseline score by 6 months after treatment. The patient-reported xerostomia, in contrast with the QoL, worsened and persisted in both arms (24, 26). Fisher et al used the University of Washington Head and Neck Symptom Scale questionnaire in their trial. Even though the unstimulated saliva increased in the pilocarpine group, no improvement in QoL during the follow-up 6 months was reported (19, 25).

**Adverse effects of pilocarpine**

Several included articles reported adverse effects of pilocarpine, including nausea, lacrimation, sweating, rhinitis, mild headache, and urinary frequency (21, 23, 26). The observed adverse effects were usually mild and tolerable. Meta-analysis was not performed because included studies failed to report quantifiable outcome measures. On the basis of the original report from the largest trial, no statistical difference was reported between the pilocarpine group and the placebo group (25). Only 1 patient receiving pilocarpine discontinued the medication because of excessive sweating (18).

**Discussion**

The efficacy of pilocarpine on the treatment of radiation-induced xerostomia has been studied since the 1990s (31). The morbidity of radiation-induced xerostomia is better avoided than treated (21). Thus, the preventive effect of
pilocarpine deserved attention through high-quality randomized, controlled trials. We searched online databases and identified 6 randomized, controlled trials in a meta-analysis, addressing this question. The results showed that concomitant administration of pilocarpine during radiation could increase the unstimulated salivary flow rate over a period of 3-6 months after treatment, alleviate the severity of clinician-rated xerostomia grade up to 6 months after treatment, and possibly relieve patient-reported xerostomia during the time frame of 6-12 months after treatment.

Our meta-analysis demonstrated that preventive pilocarpine could increase the unstimulated salivary flow rate, but the advantageous effect continued for only a period of 3-6 months. In the first 6 months, concomitant pilocarpine exhibited a favorable effect, but over time the relative

### Fig. 3. Unstimulated salivary flow rates during and after course of radiation therapy. Depicts mean differences between the pilocarpine group and the control group. Abbreviation: CI = confidence interval.

### Fig. 4. Mean difference of clinician-rated xerostomia grades between the pilocarpine group and the control group at 6 months. Abbreviation: CI = confidence interval.
increased unstimulated salivary flow rate kept descending. This phenomenon could be due to different mechanisms of salivary gland damage induced by radiation in different time phases. In the early phase after radiation, the main mechanism of xerostomia is attributable to plasma membrane damage, which could be prevented by pilocarpine or other specific receptor agonists (37). An in vivo study by Burlage et al. (34) discovered that pilocarpine could increase proliferation of undamaged cells in the early phase when there was a sufficient number of remaining progenitor cells. In the late phase (approximately 120 days later), salivary flow rate further deteriorated, because of acinar cell apoptosis and the damaged extracellular environment (35). Thus the concomitant application of pilocarpine was hypothesized to be effective only in the early phase of radiation-induced xerostomia. The protective effect may also have accounted for the decreased clinician-rated xerostomia grade at 6 months.

Although the unstimulated saliva flow improved in the pilocarpine group, pilocarpine had no effect on stimulated salivary flow rate. It was suggested that the parotid glands, which produce stimulated saliva, might be more vulnerable to radiation (36), and the recoverability of the parotid glands after radiation might be weaker than the mucous salivary glands. However, the assumption was rejected by subsequent studies (37, 38), which showed that the functional loss was quite comparable between the parotid and submandibular glands (37). The inconsistent response to pilocarpine between the unstimulated and stimulated saliva might result from the sialagogic effect of pilocarpine. The pilocarpine group, pilocarpine had no effect on stimulated salivary flow rate. It was suggested that the parotid glands, which produce stimulated saliva, might be more vulnerable to radiation (36), and the recoverability of the parotid glands after radiation might be weaker than the mucous salivary glands. However, the assumption was rejected by subsequent studies (37, 38), which showed that the functional loss was quite comparable between the parotid and submandibular glands (37). The inconsistent response to pilocarpine between the unstimulated and stimulated saliva might result from the sialagogic effect of pilocarpine. The

**Fig. 5.** Subjective xerostomia scores during and after course of radiation therapy. Depicts mean differences between the pilocarpine group and the control group. Abbreviation: CI = confidence interval.
daily administration of pilocarpine was presumed to keep
the salivary glands in the stimulated condition. When
secreting at a maximum rate, no more saliva could be
secreted even with another stimulus, hence the stimulated
saliva showed no significant change. Our finding was
similar to those from the study by Wasserman et al (39),
who observed a significant increase in unstimulated saliva
production but found no difference in stimulated saliva flow
in patients receiving the radioprotective agent of
amifostine.

With respect to the patient-reported xerostomia, pilo-
carpine alleviated symptoms at 6 months, and possibly at
12 months (although only 1 study provided 12-month
data). Considering the minimally important difference of
5-10% improvement required to prove the clinical value
of pilocarpine, the patient-reported xerostomia at 6 months was of borderline significance (40). The
discrepancy between patient-reported xerostomia and
unstimulated saliva might be attributed to the varied and
uncontrolled radiation doses of the submandibular glands
and minor salivary glands, which would affect mucin
secretion and was a critical factor for the patient-reported
xerostomia scores (11, 41-43).

Two included trials found concomitant administration of
pilocarpine during radiation therapy could not significantly
improve QoL compared with the placebo group (19, 24).
One potential reason may be that the adopted QoL ques-
tionnaire did not adequately measure xerostomia (24, 44).
Fisher et al (19) explained that the ameliorated xerostomia
was not perceived to be ideal, negatively affecting patients’
self-appraisal of their status. Another possibility is that the
radiation-induced mucositis produces similar dysfunctions
as xerostomia, and thus reduces the QoL. (19). Jellem et al
(45) evaluated patients’ xerostomia and QoL using the
Radiation Therapy Oncology Group acute morbidity
scoring criteria and the European Organization for
Research and Treatment of Cancer QLC-C30. They found a
significant impact of clinician-rated xerostomia on QoL,
and the effect size increased over time even as the inci-
dence of xerostomia decreased. The inconsistency in
different studies indicates that the correlation between
saliva flow, clinician- or patient-rated xerostomia, and QoL
is complicated and should be further clarified in future
studies.

The effect of pilocarpine on increasing unstimulated
saliva needs to be highlighted even in the IMRT era. In-
tensity modulated radiation therapy is most useful in
sparing the parotid glands (46) and can be combined with
pilocarpine to obtain a complementary outcome. Even with
IMRT, xerostomia is still a common side effect (13). Pa-
patients with N2c lymph node disease will often have mar-
ginal sparing of bilateral parotid glands, and large tumors
of base of tongue may preclude submandibular glands
sparing. Such circumstances will cause unavoidable
radiation-induced xerostomia, which underlines the role of
pilocarpine. Furthermore, IMRT produces long-term relief
of xerostomia (8), whereas pilocarpine has more of a short-
term benefit. Therefore, the combination of pilocarpine and
IMRT is promising in preventing xerostomia and warrants
further investigation.

Certain limitations in this systematic review should be
taken into account. First, the number of included studies is
limited, which underlines the necessity to combine avail-
able evidence for clinical guidance. Relevant outcomes
should be interpreted carefully, and further high-quality
trials are proposed. Second, the long-term efficacy of
pilocarpine has to be further investigated, because no study
in our analysis tracked outcomes beyond 12 months. Last,
the adopted patient-reported or clinician-rated instruments
for grading xerostomia, or the QoL questionnaires, are
diverse, bringing about difficulty in comparing studies. A
guideline concerning the design and implementation of
future clinical trials should be recommended.

Conclusions

The concomitant administration of pilocarpine during ra-
diation can increase unstimulated salivary flow rate and
reduce clinician-rated xerostomia grade after radiation. It
may also relieve patients’ xerostomia at 6 months, and
possibly at 12 months. However, it has no effects on
stimulated salivary flow rate. More high-quality trials are
needed, with standardized outcome measures including the
normalized measurement of salivary flow, clinician-rated
xerostomia grade, patient-reported xerostomia, and a
specialized QoL questionnaire.
