(Dated: August 17, 2016)

Berry phase physics is closely related to a number of topological states of matter. Recently discovered topological semimetals are believed to host a nontrivial π Berry phase to induce a phase shift of ±1/8 in the quantum oscillation (+ for hole and − for electron carriers). We theoretically study the Shubnikov-de Haas oscillation of Weyl and Dirac semimetals, taking into account their topological nature and inter-Landau band scattering. For a Weyl semimetal with broken time-reversal symmetry, the phase shift is found to change nonmonotonically and go beyond known values of ±1/8 and ±5/8. For a Dirac semimetal or paramagnetic Weyl semimetal, time-reversal symmetry leads to a discrete phase shift of ±1/8 or ±5/8, as a function of the Fermi energy. Different from the previous works, we find that the topological band inversion can lead to beating patterns in the absence of Zeeman splitting. We also find the resistivity peaks should be assigned integers in the Landau index plot. Our findings may account for recent experiments in Cd2As3 and should be helpful for exploring the Berry phase in various 3D systems.

PACS numbers: 75.47.-m, 03.65.Vf, 72.10.-d, 71.55.Ak

The Shubnikov-de Haas oscillation of resistance in a metal arises from the Landau quantization of electronic states under strong magnetic fields. The oscillation can be described by the Lifshitz-Kosevich formula [1] cos[2π(F/B + φ)], where B is the magnitude of magnetic field, and the oscillation frequency F and phase shift φ can provide valuable information about the Fermi surface topography of materials. It is widely believed that an energy band with linear dispersion carries an extra π Berry phase [2, 3], leading to phase shifts of φ = 0 and ±1/2 in 2D and 3D, respectively, compared with ±1/8 and ±5/8 for parabolic energy bands without the Berry phase (+ for hole and − for electron carriers). Topological semimetals [4–8] provide a new platform to study the nontrivial Berry phase in 3D. They have linear dispersion near the Weyl nodes at which the conduction and valence bands touch. The Weyl nodes host monopoles connected by Fermi arcs, and have been discovered in the Dirac semimetals Na3Bi [9–11] and Cd3As2 [12–19], and the Weyl semimetals TaAs family [20–29] and YbMnBi2 [30].

Exploring the π Berry phase in 3D semimetals remains difficult [31–46]. To extract the phase shift, the Landau indices, i.e., where F/B + φ takes integers n, need to be identified first from the magnetoresistivity. A plot of n vs 1/B then extrapolates to the phase shift on the n axis. However, the first step in 3D is highly nontrivial. In 3D, a magnetic field quantizes the energy spectrum into a set of 1D bands of Landau levels. There may be multiple Landau bands on the Fermi surface and scattering among them. This situation never occurs for discrete Landau levels in 2D. It is not intuitive to determine the Landau indices in 3D without a sophisticated theoretical analysis of the resistivity of the Landau bands. Both the resistivity peaks [31, 32, 34–37, 39] and valleys [41, 42, 45, 47] have been used to identify the Landau indices in different experiments. The treatments can introduce a system error of π, comparable with the π Berry phase under quest, and partially lead to a wide range of the phase shifts away from the anticipated ±1/8 in the experiments (see Sec. S1 of Ref. [48]).

In this Letter, we calculate the resistivity in both longitudinal and perpendicular magnetic fields for topological Weyl and Dirac semimetals. We clarify explicitly that the resistivity peaks appear near Landau band edges and correspond to integer Landau indices. For time-reversal symmetry broken Weyl semimetals, we find that the phase shift can go beyond known values of ±1/8 or ±5/8 and nonmonotonically approach a wide range between ±7/8 and ±9/8 near the Lifshitz point, and these values may be misinterpreted as ±1/8 in experiments. For Dirac semimetals or Weyl semimetals with time-reversal symmetry, the combined phase shift takes the discrete values of either ±1/8 or ±5/8. Moreover, a new beating pattern, due to the topological band inversion rather than Zeeman splitting, is found. Our findings may explain the positive phase shifts of electron carriers in recent experiments, and should be helpful for experiments involving the Berry phase and monopole physics in various 3D systems.

Model. - We start from a two-node Hamiltonian for a Weyl semimetal [49–51]

\[ \mathcal{H} = A(k_x \sigma_x + k_y \sigma_y) + M(k_w^2 - k^2)\sigma_z, \]

(1)

where \((\sigma_x, \sigma_y, \sigma_z)\) are the Pauli matrices, the wave vector \(k = (k_x, k_y, k_z)\), and \(A, M, \) and \(k_w\) are model parameters. The energy dispersion of the model is \(E^\pm_k = \pm [M^2(k_w^2 - k^2) + A^2(k_x^2 + k_y^2)]^{1/2}\), with ± for the conduction and valence bands, respectively. The model hosts
two Weyl nodes at \((0, 0, \pm k_w)\) [Fig. 1(a)], and has been demonstrated to carry all of the topological semimetal properties [51]. In particular, the Fermi arcs, i.e., the \(k_z\)-dependent topological edge states, can be solved analytically from the model with an open boundary condition [52], in contrast to the \(k \cdot \sigma\) model [53–55]. The topological properties of the model arise from the \(\sigma_z\)-term [56], with which the model can smoothly change from linear dispersion near the Weyl nodes to parabolic dispersion at high Fermi energies.

**Quantum oscillation in linear and parabolic limits.** In the presence of a \(z\)-direction magnetic field \(B\), the energy spectrum splits into a series of 1D bands of Landau levels [51, 52] [see Figs. 1(b)-1(c)], which give rise to the quantum oscillation. We focus on the bulk states, as the oscillation via surface states requires ultrathin films [57] and can be ignored in the work. We calculate the resistivity in two direction configurations following linear response theory [58–61] (see Sec. S2 of Ref. [48] for the calculation details). In the longitudinal configuration, resistivity is measured along the \(z\) direction (denoted as \(\rho_{zz}\)), and in the transverse configuration resistivity is measured along the \(x\) direction (\(\rho_{xx}\)). The magneto resistivity in the linear and parabolic dispersion limits can be found analytically to take the general form

\[
\left(\rho - \rho_0\right)/\rho_0 = C \exp(-\lambda_D) \cos\left[2\pi \left(\frac{F}{B} + \phi\right)\right],
\]

(2)

where subscripts \(xx\) and \(zz\) are suppressed for simplicity, \(\rho_0\) is the zero-field resistivity, \(\lambda_D\) is the Dingle factor, and \(C\) is a constant coefficient. The analytic expressions for the frequency \(F\) and phase shift \(\phi\) are listed in Table I for the two limits. We can analytically obtain the expected \(-1/8\) in the linear limit and \(-5/8\) in the parabolic limit for electron carriers. Note that the frequency in the linear limit depends not on the effective mass, but on \(A\) in the velocity term.

**TABLE I.** The analytical expressions for the frequency \(F\) and phase shift \(\phi\) in the resistivity formula Eq. (2) in the linear and parabolic dispersion limits for electron carriers. We define \(E'_F \equiv E_F + M k_w^2\).

**Resistivity peaks and integer Landau indices.** In experiments, due to sophisticated data patterns, the oscillation may not be well fitted by the Lifshitz-Kosevich form in Eq. (2). Instead, the peak or valley positions on the \(B\) axis are assigned integer Landau indices \(n\), then \(\phi\) and \(F\) can be fitted from a plot of \(n\) and \(1/B\) [see inset of Fig. 1(d)]. However, whether the peaks [31, 32, 34–37, 39] or valleys [41, 42, 45, 47] should be assigned indices is still in debate. Our results explicitly clarify that the resistivity peaks of both \(\rho_{xx}\) and \(\rho_{zz}\) appear near Landau band edges and correspond to integer Landau indices. As shown in Fig. 1, peak 5 in (d) appears when the Fermi energy is close to the band edge of the 5th Landau band [Fig. 1(b)], valley 5.5 appears when the Fermi energy lies somewhere between the 5th and 6th bands [Fig. 1(c)]. The numerical results using the peaks as integers in the Landau index plot are shown in Fig. 2. As shown in Fig. 2(c), in the limits \(E_F \to 0\) and \(\infty\), the numerical fitting can recover the analytic results of \(-1/8\) and \(-5/8\) phase shifts, respectively.

Why both \(\rho_{zz}\) and \(\rho_{xx}\) show peaks near the band edges can be explained as follows. In theory, the resistivity components are evaluated from the conductivity components [62, 63]. In the longitudinal configuration, the resistivity \(\rho_{zz}=1/\sigma_{zz}\), where \(\sigma_{zz}\) is the conductivity along the \(z\) direction. Near the band edges, because of vanishing velocities, the conductivity \(\sigma_{zz}\) shows valleys, so \(\rho_{zz}\) shows peaks. In the transverse configuration, \(\rho_{xx} = \sigma_{yy}/(\sigma_{yy}^2 + \sigma_{xy}^2)\), and the longitudinal and field-induced Hall conductivities are found as (see Sec. S3 of
The anisotropic conductivity tensor is given by

\[ \sigma_{yy} = \frac{\sigma_0 (1 + \delta)}{1 + (\mu B)^2}, \quad \sigma_{yx} = \frac{\mu B \sigma_0}{1 + (\mu B)^2} \left[ 1 - \frac{\delta}{(\mu B)^2} \right], \]

where \( \sigma_0 \) is the zero-field conductivity and \( \delta \ll 1 \) represents the oscillation part. The \( \delta \) term in \( \sigma_{yx} \) is from the disorder scattering and was seldom considered before. A consequence of the \( \delta \) term in \( \sigma_{yx} \) is that \( \rho_{xx} \approx (1 + \delta) / \sigma_0 \), up to the leading order of \( \delta \). As both \( \rho_{xx} \) and \( \sigma_{yy} \) are proportional to \( 1 + \delta \), their peaks are aligned for the arbitrary ratio of \( \sigma_{yx} \) to \( \sigma_{yy} \) (but the oscillation is too weak to be observed when \( \sigma_{yx} \ll \sigma_{yy} \)). This is a new finding as a result of the disorder scattering \( \delta \) term in the Hall conductance. Meanwhile, the \( \sigma_{zz} \) valleys are aligned with the \( \sigma_{yy} \) peaks, because \( \sigma_{zz} \) originates from diffusion and is proportional to the scattering times, while \( \sigma_{yy} \) results from hopping (i.e., off-diagonal velocities and scattering times that couple different Landau bands) and is inversely proportional to the scattering times [51, 59, 64]. Stronger scattering (i.e., shorter scattering times) can suppress diffusion but enhance hopping. In summary, the peak positions satisfy the relation \( \rho_{zz} \sim \sigma_{zz}^{-1} \sim \sigma_{yy} \sim \rho_{xx} \), so both \( \rho_{zz} \) and \( \rho_{xx} \) show peaks near the Landau band edges and share the same phase shift.

**Anomalous phase shift near the Lifshitz point.** - For a Fermi energy between the linear and parabolic dispersion limits, the phase shift is expected to change from one limit to the other. However, we find the crossover can be nonmonotonic. We numerically calculate the frequency and phase shift by fitting the Landau index plot [see inset of Fig. 1(d)] for arbitrary Fermi energy \( E_F \). Figure 2 shows the numerical results for \( F \) and \( \phi \). In Figs. 2(a) and 2(b), the comparison between the analytical [see Eq. (5) and its vicinity] and numerical results for \( F \) justifies our numerical scheme. Note that \( F \) converges because it depends only on \( A \) near the Weyl nodes and only on \( M \) at higher Fermi energies. In Fig. 2(c), the numerical results recover the analytical \( \phi = -1/8 \) in the linear limit (\( E_F \to 0 \)) and \(-5/8 \) in the parabolic limit (\( E_F \to \infty \)). For convenience, we define two energy parameters,

\[ E_A = Ak_w, \quad E_M = Mk_w^2. \quad (4) \]

For \( E_M \neq E_A \), the \( \phi \)-\( E_F \) curves break due to the formation of beating patterns, which we discuss later. In Fig. 2(c), when \( E_A < E_M \), the phase shift does not monotonically transit from \(-1/8 \) to \(-5/8 \), but drops below \(-5/8 \) in an intermediate regime around the so-called Lifshitz transition point (at which \( E_F = E_M \)). In either the linear or parabolic limit, the energy spectrum is a simple function of \( k_z^2 \), and an integral of \( k_z \) gives the extra \( \pm 1/8 \) phase compared with that in 2D. Away from the two limits, this simple \( k_z^2 \) dependence is violated, which is probably the reason for the anomalous phase shift. We can analytically show the phase shift of \(-9/8 \) at the Lifshitz point when \( E_M = E_A \) (see Sec. S4 of Ref. [48]), consistent with that in Fig. 2(c). This value is equivalent to \(-1/8 \), which is usually believed to arise from the \( \pi \) Berry phase when the Fermi sphere encloses single Weyl nodes. However, in this case, the Fermi sphere encloses two Weyl nodes with a Fermi energy at the Lifshitz point. When \( E_A > E_M \), there is no nonmonotonicity in \( \phi - E_F \).

A Weyl semimetal and its time-reversal partner can form a Dirac semimetal, whose model can be built by \( \mathcal{H}(k) \) in Eq. (1) and its time-reversal partner \( \mathcal{H}^*(-k) \), where the asterisk refers to a complex conjugate. This model can also serve as a building block for Weyl semimetals that respect time-reversal symmetry but break inversion symmetry [20–29]. For this case, there is no anomalous Hall effect. The change of phase shift of \( \mathcal{H}^*(-k) \) is opposite to that of \( \mathcal{H}(k) \), and the two give rise to a combined phase shift. If we describe the oscillation of \( \mathcal{H}(k) \) by \( \cos[2\pi(F/B + \alpha) - 1/8] \), then that of \( \mathcal{H}^*(-k) \) is \( \cos[2\pi(F/B - \alpha) - 1/8] \), and the oscillation of the Dirac semimetal behaves like \( \cos(2\pi\alpha) \cos[2\pi(F/B - 1/8)] \). According to Fig. 2(c), \( \alpha \) can vary over 1, so \( \cos(2\pi\alpha) \) may
According to our numerical results, the combined phase shift in the experiments are around $5/8$ to $-5/8$, and hence look like $1/8$ to $3/8$ because of the $2\pi$ periodicity. According to our numerical results, the combined phase shift takes these values from around the Lifshitz point to higher Fermi energies, which is also consistent with the carrier density in the experiments. In Table II, we suggest the counterparts for the experimental values of the phase shift. Nevertheless, a comparison with the TaAs family is difficult, because there are too many bands on the Fermi surface.

**Beating pattern from topological band inversion.** - Figure 3 (a) also shows that the Dirac semimetal and each of its Weyl components develop beating patterns. They are not from the Zeeman splitting, but inherited from the band inversion of the Weyl semimetal [see Fig. 1(a)]. Consequently, some Landau bands have more than one extreme point [see Figs. 1 (b)-1(c)]. We can also show that each extreme point gives rise to a resistivity peak. Then, for each Weyl component, the oscillation may have two frequencies and develop beating patterns. We find the frequency analytically. For $E_F$ below $E_A$ and $E_M$, $F = F_0 \equiv E_A^2 \hbar/2A^2e$; for $E_F$ between $E_A$ and $E_M$,

$$F = \begin{cases} F_+ \text{ and } F_0, & E_M < E_F < E_A, \\ F_+ \text{ and } F_-, & E_A < E_F < E_M; \end{cases}$$

and for $E_F$ above $E_A$ and $E_M$, $F = F_+$, where $F_+ = (\hbar/e)(E_F^2 - E_M^2)/(A^2 - 2ME_M \pm [(2ME_F^2 - (2ME_A)^2 + A^4)^{1/2}]}).$ Equation (5) indicates that the beating pattern forms only when the Fermi energy $E_F$ is between $E_M$ and $E_A$. Here, the beating pattern arises because of the topological nature of the semimetal, different from the Zeeman splitting [39, 40, 65], nested Fermi surfaces [34], and orbital quantum interference [66].

We thank P. Vasilopoulos for valuable discussions. TABLE II. The phase shift $\phi_{\text{exp}}$ extracted from the experiments on Cd$_3$As$_2$. According to the theory in this work, if peaks from two Weyl components can be distinguished, the phase shift should be $\phi_{\text{Weyl}} = \phi_{\text{exp}} - 1$; otherwise, the phase shift should be $\phi_{\text{Dirac}} = -5/8$ according to Fig. 3(b). Compared with Eq. (2), the formula used in Refs. [32] and [41] has an extra $1/2$, which has been subtracted from $\phi_{\text{exp}}$.

S1. A SURVEY OF THE PHASE SHIFT OF THE QUANTUM OSCILLATION IN EXPERIMENTS

See Table S1 for a survey of the phase shift of the quantum oscillation collected from the recent experiments.

S2. THE CALCULATION OF THE RESISTIVITY

A. Weyl semimetal without time reversal symmetry

We calculate the resistivities in both the longitudinal and transverse configurations. In the longitudinal configuration, the electric field is parallel to the magnetic field along the z direction, the resistivity

\[ \rho_{zz} = \frac{1}{\sigma_{zz}}. \]  

(S1)

TABLE S1. The oscillation of the magnetoresistance for 3D systems can be phenomenologically fitted by the Lifshitz-Kosevich formula [1, 2] \( \Delta \rho \propto \cos 2\pi(F/B + \phi) \) with \( F \) the oscillation frequency and \( \phi \) the phase shift. This table shows the phase shift \( \phi \) of magnetoresistance measured in the experiments. F# distinguishes different frequencies in the samples. S# means different samples. B and I mean the magnetic field and current directions, respectively. c and a are crystallographic axes. T means transverse configuration.

a The Seebeck effect
b The Nernst effect
c Measured using pulsed magnetic fields

* luhz@sustc.edu.cn
In the transverse configuration, the electric field is perpendicular to the magnetic field, the resistivity
\[ \rho_{xx} = \frac{\sigma_{yy}}{\sigma_{yy}^2 + \sigma_{yx}^2}. \]  
(S2)

When \( \mu B \gg 1 \), the nondiagonal conductivity \( \sigma_{yx} \approx \sigma_H \), where the Hall conductivity \( \sigma_H \) has two parts
\[ \sigma_H = \frac{ne}{B} + \frac{e^2 k_w}{\hbar \pi}. \]  
(S3)

The first term is the classical one with \(-e\) the electron charge and \( n \) the carrier density measured from the Weyl nodes, and the second term is the anomalous Hall conductance because the two-node model breaks time-reversal symmetry. We numerically evaluate \( n \) by using \( n = \sum \chi f(E_k^\pm) \) for electron carriers. For a Dirac semimetal, there is no anomalous Hall conductance if the Zeeman energy is ignorable. The nondiagonal conductivity \( \sigma_{yx} \) for general \( \mu B \) also has an oscillation part (see Sec. S3).

The conductivity \( \sigma_{zz} \) and \( \sigma_{yy} \) take the forms [12, 13]
\[ \sigma_{zz} = \frac{e^2}{k_B T} \sum_\zeta \tau_\zeta f(E_\zeta) \Big[ 1 - f(E_\zeta) \Big] v_{zz}^2, \]
\[ \sigma_{yy} = \frac{e^2}{2k_B T} \sum_{\zeta\zeta'} w_{\zeta\zeta'} f(E_\zeta) \Big[ 1 - f(E_{\zeta'}) \Big] (y_\zeta - y_{\zeta'})^2, \]  
(S4)

where \( \zeta \) represents all the quantum numbers, \( f(E) = 1/\{ \exp[(E - E_F)/k_B T] + 1 \} \) is the Fermi distribution function with \( E_F \) the Fermi energy.

\[ v_{zz} = \int \! dr \Psi_\zeta^\dagger(r) \hat{v}_z \Psi_\zeta(r) \]  
(S5)

is the diagonal matrix element of the velocity operator \( \hat{v}_z = \partial \mathcal{H}/\partial h k_z \), and \( \Psi \) is the wave function of the Landau levels [14]. The expectation value of the position \( y_\zeta = \int \! dr \Psi_\zeta^\dagger(r) y \Psi_\zeta(r) \). The transport relaxation time \( \tau_\zeta \) can be found by
\[ \frac{1}{\tau_\zeta} = \sum_{\zeta'} w_{\zeta\zeta'} \left( 1 - \frac{v_\mu_{\zeta'}}{v_{\mu\zeta'}} \right), \]  
(S6)

where the transition rate
\[ \omega_{\zeta\zeta'} = \frac{2\pi}{\hbar} \left( | \langle \Psi_\zeta | V(r) | \Psi_{\zeta'} \rangle |^2 \delta(E_\zeta - E_{\zeta'}) \right), \]  
(S7)

and \( \langle \ldots \rangle_{\text{imp}} \) means the averaging over impurity configurations. We consider the elastic impurity scattering with the potential \( V(r) = \sum \mathbf{R}_i U(|r - \mathbf{R}_i|) \), and impurities randomly distributing at positions \( \mathbf{R}_i \).

For the Landau bands used in this work, we arrive at the transition rate
\[ \omega_{\zeta\zeta'} = \frac{2\pi n_i}{\hbar} \sum_{\mathbf{q}} |u(\mathbf{q})|^2 |C_{\zeta\zeta'}(s)|^2 \delta(E_\zeta - E_{\zeta'}) \]  
(S8)

where \( u(\mathbf{q}) \) is the Fourier transform of \( U(r) \) with \( q \) wave vector, \( n_i \) is the impurity density, and the form factor \( |C_{\zeta\zeta'}(s)|^2 \) is found as
\[ |C_{\zeta\zeta'}(s)|^2 = s^{\nu_2 - \nu_1} e^{-s} \left[ \sqrt{\frac{\nu_2}{\nu_1}} \sin \theta_\zeta \sin \theta_{\zeta'} \right] \]
\[ \times L_{\nu_1 - 1}^{\nu_2 - \nu_1}(s) + \cos \theta_\zeta \cos \theta_{\zeta'} L_{\nu_1}^{\nu_2 - \nu_1}(s) \right]^2, \]  
(S9)

with \( L_{\nu_1}^{\nu_2 - \nu_1}(s) \) being associated Laguerre polynomials, \( s = \ell_B^2 (q_y^2 + q_x^2)/2 \), \( \nu_1 = \min(\nu, \nu') \), \( \nu_2 = \max(\nu, \nu') \), \( \tan \theta_{\ell_B k_z} = \left( -M_{\nu k_z} \pm \sqrt{M_{\nu k_z}^2 + \nu^2} \right)/\eta \sqrt{\nu} \), \( \nu \) denoting the Landau index, \( M_{\nu k_z} = \nu \omega_c + M(k_z^2 - k_w^2) \), \( \omega_c = 2M/\ell_B^2 \), \( \eta = \Delta V/\ell_B \), and the magnetic length \( \ell_B = \sqrt{\hbar/eB} \).

B. Dirac semimetal or Weyl semimetal with time reversal symmetry

For the model of Dirac semimetals [14, 15], the conductivities \( \sigma_{zz} \) and \( \sigma_{yy} \) are the same as Eq. (S4) except for an additional branch index from different partners in \( \zeta \). If we label the previous branch as partner 1, the second branch from the time-reversal partner \( \mathcal{H}(-\mathbf{k}) \) is labeled as partner 2. The intrabranch form factor of the first partner \( |C_{\zeta\zeta'}(s)|^2 \) is rewritten as \( |C_{\zeta_1\zeta_2}(s)|^2 \). The intrabranch form factor of the second partner \( |C_{\zeta_2\zeta_1}(s)|^2 \) is obtained by interchanging \( \cos \theta_\zeta \) and \( \cos \theta_{\zeta'} \) with \( \sin \theta_\zeta \) and \( \sin \theta_{\zeta'} \) in \( |C_{\zeta_1\zeta_2}(s)|^2 \). The interbranch form factor between two partners \( |C_{\zeta_1\zeta_2}(s, \varphi)|^2 \) is also related to the angle \( \varphi = \tan^{-1}(q_y/q_x) \), and is given by
\begin{equation}
|C_{\zeta'\zeta}(s, \varphi)|^2 = e^{-s} \left\{ s^{\nu_a-\nu_{a_1} \sin^2 \theta \zeta \nu a_2 - \nu a_1 \sin^2 \theta \zeta' \nu a_2 - \nu a_1} \right\}^2 \frac{\nu a_1! \nu a_2!}{\nu a_1! \nu a_2!} + s^{\nu b_2 - \nu b_1 \cos^2 \theta \zeta \cos^2 \theta \zeta' \nu b_2 - \nu b_1 \cos^2 \theta \zeta} \left( \nu b_2 - \nu b_1 \cos^2 \theta \zeta \right)^2 \sin 2 \theta \zeta' \sin 2 \theta \zeta \cos \left[ \tau_1 (\nu a_2 - \nu a_1) \varphi - \tau_2 (\nu a_2 - \nu a_1) \varphi \right] 
\end{equation}

\begin{equation}
\tau_1 = \begin{cases} +1, & \nu < \nu' + 1, \\ -1, & \nu > \nu' + 1, \end{cases} \quad \tau_2 = \begin{cases} +1, & \nu < \nu' - 1, \\ -1, & \nu > \nu' - 1, \end{cases}
\end{equation}

Here and \( \nu a_1 = \min(\nu - 1, \nu') \), \( \nu a_2 = \max(\nu - 1, \nu') \), \( \nu b_1 = \min(\nu, \nu' - 1) \), \( \nu b_2 = \max(\nu, \nu' - 1) \). The other interbranch form factor \( |C_{\zeta'\zeta}(s, \varphi)|^2 \) can be obtained by interchanging \( \cos \theta \zeta \) and \( \cos \theta \zeta' \) with \( \sin \theta \zeta \) and \( \sin \theta \zeta' \) in \( |C_{\zeta'\zeta}(s, \varphi)|^2 \).

C. Numerical scheme

In this work, we consider the electron conduction case at zero temperature and assume short-range scattering \( u(q) = u_0 \). In the presence of the \( z \)-direction magnetic field, we numerically calculate the resistivity \( \rho_{zz} \) in the longitudinal configuration and \( \rho_{xx} \) in the transverse configuration, with the formulas above.

In the presence of disorder, the Landau bands are broadened, inevitably. A Gaussian form broadening is modeled with a constant width \( \Gamma \). Hence, \( \delta(E_\zeta - E_F) \) is replaced by

\begin{equation}
\delta(E_\zeta - E_F) \rightarrow \sqrt{\frac{2}{\pi \Gamma^2}} \exp \left[ -\frac{2(E_\zeta - E_F)^2}{\Gamma^2} \right].
\end{equation}

In the calculation, the broadening width \( \Gamma \) is taken to be the energy interval between the valleys of \( E_{1+16} \) and \( E_{15+15} \). The scattering potential \( n_i u_0^2 = 3\pi A^2 \Gamma / E_F \alpha_T \), with \( \alpha_T = 10 \) a phenomenological parameter that relates the electron lifetime to the transport scattering time.

To eliminate the non-oscillation background, the third-order derivative of the resistivity with respect to \( B \) are evaluated. Therefore, the peaks and valleys of \( \rho_{xx} \) correspond to the zeros of \( d^3 \rho_{xx} / dB^3 \). By assigning the peaks and valleys of resistivity to be integer and half-integer indices, respectively, one obtains the Landau index plot. The slope and intercept of the plot give the oscillation frequency and the phase shift, respectively. In order to get continuous curves of the phase shift, one has to choose a gauge in which the intercept \( \phi = -1/8, -5/8 \) when \( E_F \rightarrow 0 \) and \( \infty \), respectively, for electron carriers.

S3. Phase shift of resistivity \( \rho_{xx} \) for arbitrary \( \mu B \)

For arbitrary \( \mu B \), especially \( \mu B \approx 1 \) with \( \mu \) the mobility, one has to consider the oscillation of the nondiagonal (Hall) conductivity \( \sigma_{yx} \). We will discuss this effect with the help of Green’s function formulism [16]. The tensor of the static conductivity is given by

\begin{equation}
\sigma_{\alpha\beta} = \frac{e^2 \hbar}{2\pi} \int dE f(E) \text{Tr} \left[ \left[ \hat{\nu}_\alpha \frac{\partial \hat{G}^R}{\partial \hat{E}} \hat{\nu}_\beta \left( \hat{G}^A - \hat{G}^R \right) \right. \right. \left. \left. - \left( \hat{G}^A - \hat{G}^R \right) \hat{\nu}_\beta \frac{\partial \hat{G}^A}{\partial \hat{E}} \hat{\nu}_\alpha \right] \right]_{\text{imp}}
\end{equation}

with \( \hat{G}^{R/A} \) being the retarded/advanced Green’s function, the velocity operator \( \hat{\nu}_\alpha = \partial \hat{H}/\partial \hbar \hat{\kappa}_\alpha \), where the wave vector should be replaced by \( \mathbf{k} = (k_x - eB y/\hbar, i \hat{\kappa}_y, \hat{\kappa}_z) \) under the Pierls replacement. The conductivity tensor can be calculated in the Landau band representation. The matrix elements of the velocity operator for electrons are written as

\begin{equation}
v_{x'x'} = \int d\mathbf{r} \mathbf{\Psi}_\uparrow^\dagger(\mathbf{r}) \hat{\nu}_x \mathbf{\Psi}_\downarrow(\mathbf{r})
= v_{x'x'}^{(1)} \delta_{k_x k'_x} \delta_{k_y k'_y} \delta_{n,n'-1} + i v_{x'x'}^{(2)} \delta_{k_x k'_x} \delta_{k_y k'_y} \delta_{n,n'+1},
\end{equation}

\begin{equation}
v_{y'x'} = \int d\mathbf{r} \mathbf{\Psi}_\uparrow^\dagger(\mathbf{r}) \hat{\nu}_y \mathbf{\Psi}_\downarrow(\mathbf{r})
= -i v_{x'x'}^{(1)} \delta_{k_x k'_y} \delta_{k_y k'_x} \delta_{n,n'-1} + i v_{x'x'}^{(2)} \delta_{k_x k'_y} \delta_{k_y k'_x} \delta_{n,n'+1},
\end{equation}

with

\begin{equation}
v_{x'x'}^{(1)} = Ah^{-1} \sin \theta_{+vk} \cos \theta_{+vk'z} + \sqrt{2} M \ell^{-1} \hbar^{-1} \times \left( \sqrt{\nu} - 1 \sin \theta_{+vk} \sin \theta_{+vk'z} \right.
- \sqrt{\nu} \cos \theta_{+vk} \cos \theta_{+vk'z}),
\end{equation}

\begin{equation}
v_{x'x'}^{(2)} = Ah^{-1} \cos \theta_{+vk} \sin \theta_{+vk'z} + \sqrt{2} M \ell^{-1} \hbar^{-1} \times \left( \sqrt{\nu} \sin \theta_{+vk} \sin \theta_{+vk'z} \right.
- \sqrt{\nu} + 1 \cos \theta_{+vk} \cos \theta_{+vk'z}).
\end{equation}
For simplicity, by using a constant broadening $\gamma$, the retarded/advanced Green’s function of electrons is given by

$$G^{R/A}_\nu = \frac{1}{E - E^\pm_{+\nu} \pm i\gamma}, \quad \text{(S19)}$$

where the Landau bands $E^k_{+\nu} = \omega_c/2 + \sqrt{M_{\nu}^2 + \nu\hbar^2}$ for $\nu \geq 1$, $E_0^k = \omega_c/2 + M_{0\nu}$, for $\nu = 0$, and $\gamma = \hbar/2\tau$ with $\tau$ the lifetime. Therefore, the diagonal conductivity can be obtained as

$$\sigma_{yy} = -\frac{e^3B}{4\pi^2} \int dE \frac{df(E)}{dE} \times \sum_{\nu, k_z} \left[\frac{v^{(1)}_{\nu+k_z}v^{(2)}_{\nu+1+k_z}\gamma^2}{(E - E^k_{\nu+1})^2 + \gamma^2} \right] \left[\frac{\delta}{(E - E^k_{\nu+1})^2 + \gamma^2}\right]. \quad \text{(S20)}$$

After some transformations, this conductivity can be rewritten as

$$\sigma_{yy} = -\frac{e^3B}{4\pi^2} \int dE \frac{df(E)}{dE} \times \sum_{\nu, k_z} \frac{v^{(1)}_{\nu+k_z}v^{(2)}_{\nu+1+k_z}(2\gamma)^2}{(E^k_{\nu+1} - E^k_{\nu+1})^2 + (2\gamma)^2} \times \left[\frac{2E - 3E^k_{\nu+1} + E^k_{\nu+1}}{(E - E^k_{\nu+1})^2 + \gamma^2} - \frac{2E - 3E^k_{\nu+1} + E^k_{\nu+1}}{(E - E^k_{\nu+1})^2 + \gamma^2}\right]. \quad \text{(S21)}$$

This expression can be simplified for small broadening

$$\sigma_{yy} \approx -\frac{e^3B}{4\pi^2} \int dE \frac{df(E)}{dE} \times \sum_{\nu, k_z} \frac{v^{(1)}_{\nu+k_z}v^{(2)}_{\nu+1+k_z}(2\gamma)^2}{(E^k_{\nu+1} - E^k_{\nu+1})^2 + (2\gamma)^2} \times \frac{1}{(E - E^k_{\nu+1})^2 + \gamma^2}. \quad \text{(S22)}$$

The nondiagonal Hall conductivity $\sigma_{yx}$ is expressed as

$$\sigma_{yx} = \frac{e^3B}{4\pi^2} \int dE \frac{df(E)}{dE} \sum_{\nu, k_z} L_{\nu, k_z}(E), \quad \text{(S23)}$$

with

$$L_{\nu, k_z}(E) = \int_{-\infty}^{E} dE' v^{(1)}_{\nu+k_z}v^{(2)}_{\nu+1+k_z} \times \frac{8\gamma \left[(E' - E^k_{\nu+1})^2 + (E' - E^k_{\nu+1})^2 - \gamma^2 \right]}{\left[(E' - E^k_{\nu+1})^2 + \gamma^2 \right]^2 \left[(E' - E^k_{\nu+1})^2 + \gamma^2 \right]^2}. \quad \text{(S24)}$$

After performing the above integral, the nondiagonal conductivity yields a dissipativeless part and a dissipative part,

$$\sigma_{yx} = \sigma_H - \Delta\sigma_{yx}, \quad \text{(S25)}$$

where

$$\Delta\sigma_{yx} = -\frac{e^3B}{4\pi^2} \int dEdf(E) \sum_{\nu, k_z} \frac{v^{(1)}_{\nu+k_z}v^{(2)}_{\nu+1}(2\gamma)}{(E^k_{\nu+1} - E^k_{\nu+1})^2 + (2\gamma)^2} \times \left\{ \frac{2}{(E - E^k_{\nu+1})^2 + \gamma^2} + \frac{(2\gamma)^2}{(E - E^k_{\nu+1})^2 + \gamma^2} \right\}. \quad \text{(S26)}$$

The first term in the curly braces of $\Delta\sigma_{yx}$ almost vanishes due to the summation over $\nu$. Therefore, according to Eqs. (S22) and (S26), the difference between $\sigma_{yy}$ and $\Delta\sigma_{yx}$ is only a factor $2\gamma/(E^k_{\nu+1} - E^k_{\nu+1})$ in the summation. This factor can be approximated as $1/\mu B$, then

$$\sigma_{yx} \sim \sigma_H - \frac{\sigma_{yy}}{\mu B}. \quad \text{(S27)}$$

Hence, the oscillation of $\sigma_{yx}$ differs from that of $\sigma_{yy}$ by a $\pi$ phase, and $\Delta\sigma_{yx}$ is in higher orders of $1/\mu B$. This relation is also known for conventional electron gases with parabolic band dispersion [16].

When $\sigma_{yx} \gg \sigma_{yy}$ or $\mu B \gg 1$, which holds in most experiments, the oscillation part of $\sigma_{yx}$ can be abandoned. Hence,

$$\rho_{xx} = \sigma_{yy} / \sigma_{yx}^2 \approx \frac{\sigma_{yy}}{\sigma_{yx}^2} \approx \frac{\sigma_{yy}}{\sigma_H^2} \approx \frac{\sigma_{yy}}{\sigma_H^2}, \quad \text{(S28)}$$

so $\rho_{xx}$ and $\sigma_{yy}$ are in phase.

In fact, $\rho_{xx}$ and $\sigma_{yy}$ are always in phase for any $\mu B$. To see this, for arbitrary $\mu B$, the diagonal conductivity in Eq. (S22) can always be expressed as

$$\sigma_{yy} \sim \sigma_0(1 + \delta) / \left[1 + (\mu B)^2\right], \quad \text{(S29)}$$

where $\delta \ll 1$ represents the oscillation part and $\sigma_0 = \sigma_0(1 + \delta)$ is the conductivity in the absence of magnetic field (the anomalous part of $\sigma_H$ is suppressed for simplicity). Use Eq. (S27),

$$\sigma_{yx} = \frac{\sigma_0}{\mu B} - \frac{\sigma_{yy}}{\mu B} = \frac{\sigma_0}{1 + (\mu B)^2} \times \left[1 - \frac{\sigma_0}{(\mu B)^2}\right], \quad \text{(S30)}$$

and

$$\rho_{xx} = \frac{\sigma_0(1 + \delta)}{1 + (\mu B)^2} \times \left[\frac{\sigma_0(1 + \delta)}{1 + (\mu B)^2} \times \left[1 - \frac{\sigma_0}{(\mu B)^2}\right]\right]^2 \approx \frac{1 + \delta}{\sigma_0}, \quad \text{(S31)}$$

up to the leading order of $\delta$. According to Eqs. (S29) and (S31), both $\sigma_{yy}$ and $\rho_{xx}$ are proportional to $\delta$ for arbitrary $\mu B$, so $\rho_{xx}$ is always in phase with $\sigma_{yy}$. When
\( \sigma_{yx} \ll \sigma_{yy} \), we have \( \rho_{yx} \ll \rho_{xx} \). If the oscillation of \( \sigma_{yx} \) is neglected, one could arrive at \( \rho_{xx} = \sigma_{yy}/(\sigma_{yy}^2 + \sigma_{yx}^2) = 1/\sigma_{yy} \), it seems that the oscillation of \( \rho_{xx} \) differs from that of \( \sigma_{yy} \) by a \( \pi \) phase. This conclusion is found to be wrong according to above analysis.

S4. Quantization Rule and Phase Shift at Lifshitz Point

From \( E_{F+}^{k_z} = E \), the quantization rule is given by

\[
2\pi \nu \frac{eB}{\hbar} = \pi \left\{ -\left( k_z^2 - k_w^2 + k_0^2 \right) \right\} + \frac{1}{2} \sqrt{k_0^4 + 4k_0^2(k_w^2 - k_z^2) + 4 \left( \frac{E - \omega_c/2}{M} \right)^2 }, \tag{S32}
\]

where \( k_0 \equiv A/M \). There are two situations. For this 3D case, the Landau indices also depend on the third component of the wave vector, giving a quantization rule that is beyond the Onsager’s rule. There are also \( B \)-dependent terms on the right hand side. The 0th order term of \( \omega \), leads to the area in the \( k_x-k_y \) plane by fixing \( k_z \) as a parameter; the first order term represents the magnetization; the second order term denotes the magnetic susceptibility, and so on [17]. In contrast to the linear and parabolic limits, due to the complex structure of the energy spectrum, the Landau indices now do not linearly depend on \( k_z^2 \). Hence, the \(-1/8\) phase shift originating from the simple \( k_z \) integral in the two limits is changed. As an example, we calculate the total phase shift at the Lifshitz point when \( E_M = E_A \). The oscillation part of the resistivity \( \rho_{xx} \) is written as

\[
\rho_{xx}^{\text{os}} \propto \sum_{k_z} \int dx \delta(E_{F+}^{k_z} - E_F) \cos(2\pi x). \tag{S33}
\]

When \( E_M = E_A \), only the positive branch of Eq. (S32) contributes to the resistivity. After the integration and summation, it is found that

\[
\rho_{xx}^{\text{os}} \propto \cos \left[ 2\pi \left( \frac{E_F}{\eta} \right)^2 + \pi \left( \frac{\eta}{E_F} \right)^2 + \alpha \right], \tag{S34}
\]

where

\[
\tan \alpha = \frac{1 - 2S(z)}{1 - 2C(z)}, \tag{S35}
\]

with \( S(z) \) and \( C(z) \) being the Fresnel sine and cosine integrals, \( z = \sqrt{\xi^2 - 4k_z^2 + 1}/\xi \), and \( \xi = \eta/E_F \). To the lowest order of \( \xi \),

\[
\rho_{xx}^{\text{os}} \propto \cos \left[ 2\pi \left( \frac{E_F^2}{\eta^2} - \frac{9}{8} + O(\xi) \right) \right]. \tag{S36}
\]

The phase shift at the Lifshitz point is a universal value to the lowest order of \( \xi \). This is in consistence with the numerical results. This value of the phase shift at the Lifshitz point verifies the non-monotonic behavior of the phase shift as a function of the Fermi energy.
