Abstract

Study Design: Case Report

Objective: To highlight the importance of preventing visceral injury due to prominent anterior implants to the spinal column.

Summary of Background Data: Spinal cord decompression through a thoracotomy approach is a commonly performed procedure. Postoperative hemothorax is a rare complication but if it occurs, requires urgent attention and reoperation.

Methods: A 52-year-old man with cord compression was treated with a T9/10 discectomy and instrumented fusion via a right thoracotomy and trans-pleural approach. Postoperatively he had improved lower limb numbness. However, after a bout of coughing, there was sudden increase in chest drain output, hemodynamic instability and massive fluid collection in the right chest cavity.

Results: Emergency re-exploration of the thoracotomy was performed and a 6 cm laceration of the right postero-medial diaphragm was identified as the bleeding source and was in close
proximity with the locking nut of the anterior implants. The laceration was repaired and a soft synthetic patch was used to cover the implants. Postoperatively, the hemothorax resolved and the patient recovered from the neurological deficit.

**Conclusions:** Prevention of diaphragmatic injury can be performed by using lower profile and less sharp-edged implants or covering the implants with a soft synthetic material if unable to perform direct repair of the parietal pleura.

**Key Words:** Hemothorax; anterior spinal fusion; diaphragm; parietal pleura

**Key Points:**

1. Hemothorax may occur as a result of diaphragmatic laceration after anterior spinal fusion.

2. Low-profile implants should be used in anterior instrumentation.

3. Good coverage of implants with the parietal pleura is advised and a soft synthetic patch should be used to cover implants in case the parietal pleura coverage is inadequate.

**Mini Abstract:**

We report a case of acute diaphragmatic laceration with hemothorax caused by
prominent and sharp anterior spinal instrumentation which required re-exploration, repair and
soft synthetic patch coverage of the implants. Low-profile implants and good coverage of
implants with the parietal pleura is advised for lower thoracic anterior instrumentation.

Introduction

Spinal cord decompression by discectomy and instrumented fusion through a thoracotomy approach is a commonly used procedure.\textsuperscript{1,2} Postoperative spontaneous hemothorax is a known but rare complication after this transpleural approach to the thoracic spine.\textsuperscript{3-5} It may be caused by re-bleeding of the epidural vessels, oozing from the exposed bone surfaces, inadvertent lung laceration or vascular injury. These causes are usually identified intraoperatively or in the immediate postoperative period. However, late presentation up to 10 months postoperatively have been reported due to the violation of inferior phrenic artery by the anterior instrumentation.\textsuperscript{4} Delay in diagnosis of early hemothorax is unlikely because of obvious clinical manifestations like high chest drain output, hemodynamic instability and drop in hemoglobin level. A simple chest X-ray (CXR) can easily confirm the diagnosis of hemothorax.

We report a case of early spontaneous hemothorax caused by a diaphragmatic laceration from anterior instrumentation. This case report serves the purpose of reminding surgeons to identify and prevent potential visceral injury intraoperatively. This can be done by either
using lower profile and less sharp-edged implants or covering the implants with soft synthetic material if the parietal pleura closure cannot provide adequate coverage of the implants. During exploration of a postoperative hemothorax, meticulous examination of the diaphragmatic surface opposing the implants is necessary to control the possible sources of hemorrhage.

**Case report**

A 52-year-old man with history of thoracolumbar back pain for many years was admitted because of spontaneous onset of gradual lower limb weakness and numbness for three days. The right lower limb was 3/5 by Medical Research Council grading (MRC grading) whereas the left side remained 5/5. Sensory level was at T11 and the sensation in both lower limbs was affected. He also had unsustainable ankle clonus and up-going Babinski sign in the right lower limb. He did not have sphincter dysfunction and his anal tone was intact. X-ray examination of the thoracic and lumbar spine was unremarkable. MRI revealed T9/10 prolapsed intervertebral disc causing spinal cord compression with myelomalacic changes (**Figures 1a and 1b**).

Urgent anterior T9/10 discectomy and instrumented fusion was performed through a right T8 thoracotomy and trans-pleural approach. At the end of the surgery, the implants (Universal Spinal System Anterior, Synthes®) could only be covered partially by the parietal
pleura due to the bulkiness of the implants and no additional mobilization of the parietal pleura. The thoracotomy was then repaired over one chest tube. The patient reported reduced numbness at lower limbs immediately after the surgery. No hemothorax was seen on plain chest radiograph CXR 6 hours after the surgery (Figures 2a and 2b) and the chest drain output was only 100ml. He was hemodynamically stable at the time.

The patient subsequently coughed vigorously due to sputum retention and reported immediate retrosternal pain. Thereafter, the chest drain output increased to 1200ml in 8 hours and his blood pressure became labile. Repeat CXR 14 hours after the initial operation showed significant fluid accumulation inside the right thorax (Figure 2c). Together with the rapidity of onset following bouts of heavy coughing, hemothorax was highly suspicious. He was immediately taken back to the operation theater for re-exploration of the right thoracotomy.

While re-opening the thoracotomy, the patient had hiccoughs despite of general anesthesia. A right postero-medial diaphragmatic laceration of about 6 cm opposing the spinal implant was found with active bleeding (Figures 3a and 3b). The laceration was repaired and the spinal implants were covered by a synthetic dural patch (Neuro-Patch®, Aesculap Inc.) to prevent any further laceration of the diaphragm (Figure 3c). Old blood clots were removed from the pleural cavity and the thoracotomy was repaired over two chest tubes.

The subsequent chest drain output was not excessive and the chest tubes were removed on day 4 after the second surgery. CXR taken one week after the re-exploration revealed no
Diaphragmatic laceration after ASF

recurrent hemothorax and the postoperative thoracic spine x-ray demonstrated satisfactory implant position (Figures 4a and 4b). The patient had near-full neurologic function two weeks after the spinal cord decompression and was able to walk independently without any aids.

Discussion

The diaphragm is a dome-shaped muscle that is important for respiration. During inspiration, the muscle contracts and the dome flattens. As a result, the intra-thoracic volume is increased and the intra-thoracic pressure is decreased with passive air entry into the lungs. During expiration, the diaphragmatic muscles relax and the dome shape is resumed. This increases the intra-thoracic pressure and air is expelled from the chest cavity. When the diaphragm is in its dome shape, the peripheral muscular part is in close proximity with the lower chest wall and the lower thoracic spine. During the coughing effort, the intra-thoracic pressure is greatly increased by the contraction of the abdominal muscles. This increase in intra-abdominal pressure causes a rigorous upward thrusting of the diaphragm which expels the air out of the lungs in an effort to cough up sputum. Such violent upward thrust of the diaphragm induces a strong gliding movement between the lower thoracic spine and the diaphragm. Any hard prominent object in its path will impede this smooth gliding motion and may even lacerate the diaphragm. Both hemi-diaphragms move across a few intercostal...
spaces within a single breathing cycle. The right hemi-diaphragm usually lies on a more rostral position due to the underlying liver. In addition, there are regional differences in the movement of the right hemi-diaphragm. The middle and posterior thirds of the right hemi-diaphragm have greater excursion than the anterior third. As a result, the posterior part of the right hemi-diaphragm is prone to injury by prominent implants inserted in the lower thoracic spine.

Under normal circumstances, gliding movement within the pleural cavity has minimal friction due to the smooth surfaces between the parietal and visceral pleura as well as the lubricating pleural fluid. Although it is desirable to repair the parietal pleura to provide a barrier between the implants and the pleural cavity, it is not always feasible due to the bulkiness of the implants and relative inelasticity of the pleura. Possible solutions include mobilizing a larger area of parietal pleura to close the pleural cavity over the implants or use a smooth synthetic patch to cover the implants. This avoids violation of the nearby lung or diaphragm by the edge of the implants. Furthermore, lower profile implants facilitate complete closure of the parietal pleura.

Postoperative diaphragmatic laceration due to anterior lower thoracic spinal instrumentation has not been reported previously. Theoretically, instrumentation on the right side with chest tube insertion may be additional risk factors for the scenario presented in our case. On the right side, the liver may push the right hemi-diaphragm hard against the
prominence of the lower thoracic implants. Hence, a left-sided approach may be safer. However, since the weakness of the patient was on the right side, right sided approach offered direct decompression. In addition, chest tube insertion often induces considerable pain during breathing. To minimize such pain, patients may use more diaphragmatic breathing and the diaphragm may rub again the implants more. Whether this postulation is true and makes patients more susceptible to diaphragmatic injury requires further study.

It is difficult to be completely sure whether the diaphragmatic laceration was not caused by other reasons such as intraoperative inadvertent injury. However, the circumstantial evidence and timing of the hemothorax supports our postulation. The early CXR did not reveal any hemothorax and the chest drain was minimal after surgery. Yet, subsequent to the patient’s episode of vigorous cough and retrosternal pain, the hemodynamics became labile, chest drain output increased significantly and a massive hemothorax was detected in the following CXR. Furthermore, hiccough appeared during the re-exploration which indicates diaphragmatic irritation.

Conclusion

Surgeons should select low profile implants at the lower thoracic spine for the anterior instrumentation. Complete coverage of implants by repair of the parietal pleura is desirable. In case of incomplete coverage due to tight or friable parietal pleura, surgeons should
consider using a smooth synthetic substance to cover the implants. A left sided approach may be safer but the choice of approaching sides may be dictated by the pathology.
