Cancer cells preferentially utilize glucose and glutamine, which provide macromolecules and antioxidants that sustain rapid cell division. Metabolic reprogramming in cancer drives an increased glycolytic rate that supports maximal production of these nutrients. The folate cycle, through transfer of a carbon unit between tetrahydrofolate and its derivatives in the cytoplasmic and mitochondrial compartments, produces other metabolites that are essential for cell growth, including nucleotides, methionine, and the antioxidant NADPH. Here, using hepatocellular carcinoma (HCC) as a cancer model, we have observed a reduction in growth rate upon withdrawal of folate. We found that an enzyme in the folate cycle, methylenetetrahydrofolate dehydrogenase 1-like (MTHFD1L), plays an essential role in support of cancer growth. We determined that MTHFD1L is transcriptionally activated by NRF2, a master regulator of redox homeostasis. Our observations further suggest that MTHFD1L contributes to the production and accumulation of NADPH to levels that are sufficient to combat oxidative stress in cancer cells. The elevation of oxidative stress through MTHFD1L knockdown or the use of methotrexate, an antifolate drug, sensitizes cancer cells to sorafenib, a targeted therapy for HCC. Taken together, our study identifies MTHFD1L in the folate cycle as an important metabolic pathway in cancer cells with the potential for therapeutic targeting.
partments are intimately linked by the transportation of serine, glycine, and formate across the mitochondrial membrane (Figure 1). The continuous cyclical movements in 2 compartments generate many metabolites essential for cell growth. The cytoplasmic folate cycle intermediate 10-CHO-THF is required for purine synthesis, while CH$_2$-THF is required for deoxythymidine monophosphate (pyrimidine) synthesis. CH$_3$-THF is then connected to the methionine cycle, where the 1C unit from CH$_2$-THF is donated to homocysteine, generating methionine, the donor of S-adenosylmethionine for DNA and histone methylation. Importantly, the folate cycle is an important source of NADPH (8), a major cellular antioxidant. Stable isotope tracing experiments have demonstrated that a majority of 1C units (>75%) entering the cytoplasmic methionine cycle were derived from the mitochondria, further confirming the connection of 2 compartments (9). MTHFDIL is the enzyme catalyzing the last step of the mitochondrial compartment generating formate and could subsequently enter the cytoplasmic compartment. MTHFDIL therefore plays critical roles in folate cycle maintenance (10).

Despite the importance of MTHFDIL in the folate cycle, knowledge about its roles in human diseases, especially cancer, remains largely elusive. Farber made the first observation in 1949 that leukemic cell growth was stimulated by folic acid while folic acid antagonists resulted in temporary remissions in patients with acute leukemia (11). His important discovery on the roles of folate in cancer provided the foundation of the development of chemotherapeutic agents as single or combined treatments for cancer (11). Homozygous Mthfd1l-knockout mice exhibited fetal growth delay, neural tube and craniofacial abnormalities, and embryonic lethality (12). In humans, MTHFD1L polymorphisms are closely related to neural tube defects, coronary artery disease, and Alzheimer’s disease (13–15). Two microarray gene expression profile studies briefly revealed that MTHFD1L was overexpressed in colorectal and breast cancers (16, 17). Discovered in breast cancer cells, miR-9 and miR-197 inhibited MTHFD1L through interacting with its 3′-UTR (18, 19). A recent metastudy including microarray data from more than 1,900 tumor tissues of 19 different cancer types suggested that the mitochondrial 1-carbon metabolism is the most deregulated metabolic pathway in human cancers (20). Intriguingly, SHMT2 and MTHFD2 were found to be overexpressed in multiple human cancers and were correlated with shorter survival in breast cancer patients (16, 20, 21). Knockdown of MTHFD2 in breast cancer cells suppressed proliferation and induced apoptosis (20). Multiple studies indicated that the folate cycle is an important metabolic pathway crucial to cancer growth (11, 20, 22–24). A recent study showed that the folate cycle, through NADPH production, enabled melanoma cells to endure oxidative stress during metastasis (25).

Hepatocellular carcinoma (HCC), a malignancy transformed from hepatocytes, accounts for 90% of primary liver cancers. HCC is the fifth most common and second most fatal cancer worldwide. Owing to late symptom presentation, most HCC patients are diagnosed at advanced stages when surgical treatments are deemed unsuitable. Currently, the only FDA-approved targeted therapy for HCC patients, a multikinase inhibitor known as sorafenib, prolongs their lifespan for a mere 3 months (26, 27). A better therapeutic regimen is warranted. The liver is a meta-
Figure 2. The folate cycle in cancer. (A) An HCC cell line, MHCC97L, was cultured in complete MEM (2 μM folate) and folate-free MEM, and cell numbers were recorded by cell counter. (B) Different HCC cell lines, MHCC97L, PLC/PRF/5, Huh7, HepG2, and Hep3B, were cultured in MEM containing different concentrations of folate, and BrdU uptake was recorded. (C) MTHFD1L mRNA expression in 16 cases of human HCC and paired nontumorous liver (NT) tissues was detected by transcriptome (RNA) sequencing. FPKM, fragments per kilobase of exon per million fragments mapped; HKU, University of Hong Kong. (D) Left: MTHFD1L mRNA expression in 85 cases of human HCC and paired NT tissues was detected by reverse transcription quantitative PCR (RT-qPCR). Values were calculated based on the following formula: 2^{-\text{Ct of MTHFD1L} - \text{Ct of 18S}}, where Ct is the cycle threshold. Right: Waterfall plot demonstrated that MTHFD1L overexpression was found in 50.59% (43/85) of HCC cases. (E) MTHFD1L mRNA expression in 49 human HCC cases from TCGA. RSEM, RNA-Seq expression estimation by expectation maximization. (F) Analysis of TCGA data revealed that HCC patients with high MTHFD1L expression (Z score > 1) were significantly associated with poorer overall and disease-free survival. (G) MTHFD1L protein expression in 3 representative HCC cases. (H) MTHFD1L mRNA expression in 8 other solid cancers from the TCGA database. A and B: Results are representative of 3 independent experiments. Error bars indicate mean ± SEM. *P < 0.05, **P < 0.01, ***P < 0.001 vs. folate depletion control. A, C, D, and H: Student’s t test. B: 1-way ANOVA. E: Wilcoxon signed-rank test. F: Kaplan-Meier followed by log-rank test.

Results

MTHFD1L in the folate cycle is significantly overexpressed in human cancers. To understand whether HCC cell proliferation relies on the folate cycle, we cultured an HCC cell line, MHCC97L, in complete medium and folate-depleted medium. Depletion of folate significantly impaired the proliferation rate of MHCC97L (Figure 2A). To confirm that this observation was not cell line-specific, we performed BrdU proliferation assay in MHCC97L as well as 4 additional HCC cell lines, PLC/PRF/5, Hep7, HepG2, and Hep3B. Folate depletion significantly reduced BrdU uptake in different HCC cell lines, further suggesting folate as an important nutrient supporting HCC growth (Figure 2B). To gain insights on the clinical significance of the folate cycle in human HCC, we examined the expression of folate cycle enzymes by transcriptome sequencing in 16 pairs of human HCC and nontumorous liver tissues. Intriguingly, transcriptome sequencing in a small cohort of HCC patients revealed that a critical enzyme connecting the mitochondrial and cytoplasmic compartments of the folate cycle, MTHFDIL, was significantly overexpressed in HCC (Figure 2C). We confirmed MTHFDIL overexpression in an expanded cohort of 85 HCC patients by reverse transcription quantitative PCR (Figure 2D). MTHFDIL overexpression was present in 50.59% (43/85) of HCC patients by at least 2-fold (Figure 2D). HCC transcriptome sequencing data available in The Cancer Genome Atlas (TCGA) echoed our findings from in-house expression data (Figure 2E). From our in-house HCC samples, we found that MTHFDIL overexpression was closely associated with aggressive clinicopathological features of HCC including the presence of tumor microsatellite formation, venous invasion, and more advanced tumor stages (Table 1). TCGA data revealed that HCC patients with high MTHFDIL expression also have lower overall and disease-free survival rates (Figure 2F).

Knockdown of MTHFDIL impedes HCC proliferation through induction of oxidative stress and ROS-associated cell cycle delay. To understand the functions of MTHFDIL, we generated MTHFDIL-overexpressing MHCC97L cells using CRISPR-
the metabolic vulnerabilities created by MTHFD1L knockdown would affect the proliferative output of HCC cells in vitro. As anticipated, knockdown and knockout of MTHFD1L significantly repressed proliferation of MHCC97L cells (Figure 5C and Supplemental Figure 1B). To confirm that our observation was not cell line–specific, we generated MTHFD1L-knockdown clones in 3 additional HCC cell lines, PLC/PRF/5, HepG2, and Hep3B (Supplemental Figure 2). Consistently, we found that knockdown of MTHFD1L caused ROS accumulation and repressed HCC proliferation in multiple HCC cell lines. We proceeded to ask whether ROS accumulation caused by MTHFD1L knockdown affects the cell cycle profile of HCC cells. HCC cells were first synchronized with nocodazole in the G2/M phase (Supplemental Figure 3). Cells were then released from nocodazole treatment. Propidium iodide staining showed that a greater percentage of MTHFD1L-knockdown and -knockout cells remained in the G1 phase relative to nontarget control (NTC) cells (Figure 5, D and E; Supplemental Figure 1C; and Table 2). Administration of different antioxidants, reduced glutathione (GSH and GSH-EE) and N-acetylcysteine (NAC), allowed the reentry of MTHFD1L-knockdown cells into the S and G2/M phases (Figure 5, D and E). MTHFD1L-mediated cell cycle delay was thus confirmed to be caused by ROS accumulation. We further confirmed that GSH could reduce ROS accumulation in MTHFD1L-knockdown cells (Figure 5F). BrdU proliferation assay further showed that GSH could partially rescue the proliferative deficiency of MTHFD1L-knockdown HCC cells (Figure 5G).

dCas9 SAM system (Figure 4A). As a result of MTHFD1L overexpression, we found that MTHFD1L increased the intracellular NADPH/NADP+ ratio and reduced intracellular ROS level (Figure 4, B and C). Reversely, we also generated MTHFD1L-knockdown MHCC97L cells (Figure 4D) and found that knockdown of MTHFD1L reduced the intracellular NADPH/NADP+ ratio, leading to the accumulation of ROS (Figure 4, E and F). Knockout of MTHFD1L by CRISPR-Cas9 gene editing system in MHCC97L and PLC/PRF/5 cells consistently reduced the intracellular NADPH/NADP+ ratio and increased intracellular ROS level (Figure 4, G–L). ROS induces DNA damage by incorporating into the DNA of the cells to form 8-hydroxy-2-deoxyguanosine (8-OH-dG). We found that DNA of the MTHFD1L-knockdown and -knockout cells contained a higher level of 8-OH-dG (Figure 5A and Supplemental Figure 1A; supplemental material available online with this article; https://doi.org/10.1172/JCI90253DS1).

Next, we evaluated the mitochondrial functions of MTHFD1L-knockdown cells by the XFp Cell Mito Stress Test, in which oligomycin, FCCP, and antimycin A and rotenone were sequentially added to the cells. As these drugs target different parts of the electron transport chain, oxygen levels detected at different drug injection time points generate a mitochondrial respiration profile that reflects the mitochondrial activity (Figure 5B). Noticeable reductions of basal respiration (oxygen consumption) and respiratory chain capacity as a result of MTHFD1L knockdown indicated the importance of MTHFD1L in maintaining proper mitochondrial function (Figure 5B). We further asked whether the metabolic vulnerabilities created by MTHFD1L knockdown would affect the proliferative output of HCC cells in vitro. As anticipated, knockdown and knockout of MTHFD1L significantly repressed proliferation of MHCC97L cells (Figure 5C and Supplemental Figure 1B). To confirm that our observation was not cell line–specific, we generated MTHFD1L-knockdown clones in 3 additional HCC cell lines, PLC/PRF/5, HepG2, and Hep3B (Supplemental Figure 2). Consistently, we found that knockout of MTHFD1L caused ROS accumulation and repressed HCC proliferation in multiple HCC cell lines. We proceeded to ask whether ROS accumulation caused by MTHFD1L knockdown affects the cell cycle profile of HCC cells. HCC cells were first synchronized with nocodazole in the G2/M phase (Supplemental Figure 3). Cells were then released from nocodazole treatment. Propidium iodide staining showed that a greater percentage of MTHFD1L-knockdown and -knockout cells remained in the G1 phase relative to nontarget control (NTC) cells (Figure 5, D and E; Supplemental Figure 1C; and Table 2). Administration of different antioxidants, reduced glutathione (GSH and GSH-EE) and N-acetylcysteine (NAC), allowed the reentry of MTHFD1L-knockdown cells into the S and G2/M phases (Figure 5, D and E). MTHFD1L-mediated cell cycle delay was thus confirmed to be caused by ROS accumulation. We further confirmed that GSH could reduce ROS accumulation in MTHFD1L-knockdown cells (Figure 5F). BrdU proliferation assay further showed that GSH could partially rescue the proliferative deficiency of MTHFD1L-knockdown HCC cells (Figure 5G).
Figure 4. MTHFD1L increased NADPH/NADP⁺ levels and reduced ROS. (A) MTHFD1L-overexpressing (OE) HCC cells were established by CRISPR-dCas9 SAM system. mRNA and protein expressions of MTHFD1L in MHCC97L-MTHFD1L-OE stable cells that express single guide RNA (sgRNA) targeting MTHFD1L and MHCC97L-NTC stable cells that express nontarget control (NTC) sgRNA. (G) MTHFD1L-knockout (KO) MHCC97L cells were established by CRISPR-Cas9 system. MTHFD1L protein expression in MHCC97L stable cells expressing empty vector control (EV) and sgRNA against MTHFD1L (ML-KO). (H) Levels of NADPH/NADP⁺ in MHCC97L-EV and -MTHFD1L-KO (ML-KO) stable cells. (I) Levels of intracellular ROS in MHCC97L-EV and -MTHFD1L-KO (ML-KO) stable cells. (J) MTHFD1L-knockout (KO) PLC/PRF/5 cells were established by CRISPR-Cas9 system. MTHFD1L protein expression in PLC/PRF/5 stable cells expressing empty vector control (EV) and sgRNA against MTHFD1L (ML-KO). (K) Levels of NADPH/NADP⁺ in PLC/PRF/5-EV and MTHFD1L-KO (ML-KO) stable cells. (L) Levels of intracellular ROS in PLC/PRF/5-EV and -MTHFD1L-KO (ML-KO) stable cells. Results are representative of 3 independent experiments. Error bars indicate mean ± SEM. *P < 0.05, **P < 0.01, ***P < 0.001 vs. NTC or EV. A–C, H, I, K, and L: Student’s t test. D–F: 1-way ANOVA.
Knockdown of MTHFD1L alters the metabolic program of HCC cells. To perceive the metabolic impacts of MTHFD1L on cancer cells, metabolomic profiling using capillary electrophoresis time-of-flight mass spectrometry (CE-TOFMS) was performed on MHCC97L-NTC and -shMTHFD1L cells (Supplemental Figure 4). Knockdown of MTHFD1L greatly altered the metabolic profiles of HCC cells (Supplemental Figure 4A). Principal component analysis demonstrated that the extractions were consistent in the triplicates of each group (Supplemental Figure 4B). Strikingly, the knockdown of MTHFD1L caused accumulations of glyceraldehyde 3-phosphate (G3P), 3-phosphoserine (3PSer), and serine. As a serine molecule is required to initiate the folate cycle (Figure 6A), MTHFD1L knockdown resulted in the truncation of the folate cycle, thus blocking the transfer of a carbon unit from serine to THF, ultimately causing an accumulation of serine and 3PSer (Figure 6B).

Interestingly, the glycolytic intermediates glucose 1-phosphate, glucose 6-phosphate, fructose 6-phosphate, fructose 1,6-bisphosphate, pyruvate, and lactate accumulated in MTHFD1L-knockdown HCC cells, suggesting a coordination between the folate cycle and glycolysis (Figure 6B. Another notably interesting pattern of metabolic changes in the TCA cycle was observed in the MTHFD1L-knockdown HCC cells (Figure 6C). We found that the levels of TCA cycle metabolic intermediates derived from pyruvate/acyetyl-CoA, including citrate, cis-aconitate, and isocitrate, decreased (Figure 6D). Meanwhile, the levels of TCA
cycle metabolic intermediates that could be derived from glutamine, including α-ketoglutarate, succinate, fumarate, malate, and oxaloacetate, increased (Figure 6D). This suggested that glutamine might replenish the TCA cycle to compensate for the effects of folate cycle defect. Unexpectedly, levels of nucleotides as well as methionine and its derivative S-adenosylmethionine were not decreased upon knockdown of MTHFD1L (Supplemental Figure 5, A and B). NADPH is required for lipid synthesis, which supports HCC development (30–32). We performed Oil Red O staining to quantitate the levels of triglycerides and lipids in the MTHFD1L-knockdown HCC cells and in HCC tumors treated with antifolate drug (methotrexate, MTX); however, no significant difference in lipid metabolism could be detected (Supplemental Figure 5, C and D). Our data suggested that the folate cycle is mainly used for oxidative stress defense in HCC cells.

**Inhibition of the folate cycle sensitizes HCC cells to sorafenib treatment in vitro.** Sorafenib is the only FDA-approved drug for HCC patients. Our next question was whether the inhibition of the folate cycle would sensitize HCC cells to sorafenib treatment. Sorafenib almost completely retarded the proliferation of MTHFD1L-knockdown HCC cells (Figure 7A). Furthermore, oxidative stress was further elevated by sorafenib in the MTHFD1L-knockdown HCC cells (Figure 7B). More strikingly, sorafenib increased the percentage of apoptotic cells in the MTHFD1L-knockdown HCC cells (Figure 7C). To achieve folate cycle suppression through pharmacological inhibition, the effects of MTX in HCC were investigated. We found that MTX was able to act synergistically with sorafenib to suppress HCC cell proliferation in vitro (Figure 7D). Oxidative stress was also profoundly induced by sorafenib in MTX-treated cells (Figure 7E). Consistent with the knockdown of MTHFD1L, sorafenib significantly elevated apoptosis in HCC cells that were treated with MTX (Figure 7F).

**Inhibition of the folate cycle represses HCC growth and sensitizes HCC cells to sorafenib treatment in vivo.** To examine whether the metabolic defects elicited by MTHFD1L knockdown inhibit HCC progression in vivo, we performed orthotopic liver implantations with MHCC97L-NTC and -shMTHFD1L cells. Six weeks after implantation, not only did we find that knockdown of MTHFD1L in HCC cells profoundly suppressed the growth of primary tumors (Figure 8A); the incidence of lung metastasis was noticeably reduced (Figure 8B). Ex vivo imaging showed that lung metastasis was found in 0 of 6 mice and 1 of 6 mice in the 2 MTHFD1L-knockdown groups as opposed to its occurrence in 5 of 6 mice from the NTC group (Figure 8B). Histological analysis suggested that tumors derived from MHCC97L-NTC cells were more aggressive than those derived from MHCC97L-shMTHFD1L cells. Many of the tumors derived from the inoculation of MTHFD1L-knockdown cells were encapsulated and regular, while all tumors derived from control HCC cell inoculation exhibited invasive tumor growth fronts (Figure 8C and Table 3). Furthermore, many necrotic regions could be found in the tumors derived from the MTHFD1L-knockdown cells, suggesting that MTHFD1L-knockdown HCC cells could not survive as well as the control HCC cells. In line with the in vitro data, we found that HCCs with knockdown of MTHFD1L were more sensitive to sorafenib in a subcutaneous tumor model (Figure 8, D–F). Next, we investigated whether pharmacological inhibition of the folate cycle by MTX would sensitize HCC cells to sorafenib treatment. MTX worked synergistically with sorafenib to suppress the growth of subcutaneous HCC tumors derived from MHCC97L as well as patient-derived tumor xenografts in nude mice (Figure 9, A–F). To further confirm our observation in immune-competent mice, we orthotopically implanted a mouse HCC cell line (Hepa 1-6) derived from C57BL/6 mouse background into the livers of C57BL/6 mice. Consistently, we observed synergism between MTX and sorafenib (Figure 9, G and H). MTX and sorafenib treatments are well tolerated in mice (Supplemental Figure 6), highlighting the translational value of this new therapeutic regimen for HCC patients.

**Discussion**

Over the past decade, research efforts have been devoted to understanding the metabolic advantages of the Warburg effect. Extensive studies focused on particularly the molecular alterations that drive the metabolism of glucose, the major nutrient and participant of the Warburg effect. On the other hand, folate, a major precursor for the folate cycle belonging to the 1-carbon metabolism, received very little attention. The folate cycle is critical for maintenance of various biological events, such as epigenetic modifications, nucleotide synthesis, and antioxidant productions. Driven by our initial observation of growth impairment in folate-depleted HCC cells, we sought to understand the regulation and roles of the folate cycle in HCC development. In this study, we first demonstrated that the major function of the folate cycle in HCC cells is redox maintenance. We demonstrated that a crucial folate cycle component, MTHFD1L, was frequently upregulated in human cancers under the control of NRF2. Knockdown or knockout of MTHFD1L effectively reduced NADPH level and caused ROS accumulation and ROS-associated cell cycle delay, as well as HCC growth hindrance in vitro and in vivo.

NADPH serves as an antioxidant molecule by maintaining glutathione and thioredoxin in reduced states, allowing donation of their electrons to stabilize ROS. NADPH is produced by 4 groups of enzymes: (a) glucose 6-phosphate dehydrogenase (G6PD), (b) malic enzymes, (c) isocitrate dehydrogenases (IDHs), and (d) MTHFDs. The first 3 groups of enzymes are tightly linked with glucose metabolism, and their involvements in cancer development are well documented. However, little information could be found for MTHFDs. G6PD, a key enzyme in the pentose phosphate pathway (PPP), was overexpressed in HCC owing to the inactivation of PTEN (33). Malic enzymes were overexpressed in human HCC (34) and were found to be repressed by p53 in osteosarcoma cells (35). IDH mutations are frequent in cancers, and IDH mutants have altered enzymatic activities causing the conversion of α-ketoglutarate to an oncometabolite, 2-hydroxyglutarate (36), leading to aberrant histone and DNA methylations in the cancer genome (37). Notably, all IDH mutations are heterozygous (38, 39), meaning the NADPH-producing ability of wild-type IDH
Figure 7. Genetic knockdown of MTHFD1L and pharmacological inhibition of the folate cycle sensitized HCC cells to sorafenib treatment via enhancing oxidative stress. is retained. Our report provides clear evidence that cancer cells rely on folate-derived NADPH. Consistent with the computational analysis predicting that the largest proportion of NADPH (~40%) in human proliferating cells comes from the folate cycle (8), our study confirms that the folate cycle plays a major role in oxidative stress defense in cancer while introducing an essential metabolic pathway for cancer growth.

Initiation of the folate cycle begins when serine reacts with THF. Serine can be either taken up exogenously or synthesized de novo from glucose, the latter suggesting a connection between the folate cycle and glucose metabolic pathways. G3P derived from glucose through glycolysis is converted to 3-phosphoglycerate, which is later converted to serine through 3 enzymes: phosphoglycerate dehydrogenase (PHGDH), phosphoserine aminotransferase (PSAT), and phosphoserine phosphatase (PSPH). A recent study showed that all the 3 serine biosynthetic enzymes were induced by c-MYC under nutrient starvation and were crucial to HCC growth (40). Our metabolomics data confirmed that serine accumulated upon knockdown of MTHFD1L, suggesting that the folate cycle indeed coordinates with serine and glucose metabolism to support cancer growth. A recent study showed that ATF4 bound with NRF2 to transcriptionally activate PHGDH, PSAT, and PSPH (41). It is possible that MTHFD1L knockdown elevated ROS, which further stabilized NRF2, leading to the ATF4-associated activation of serine biosynthetic enzymes and subsequently serine accumulation. Another study showed that mTORC activated ATF4 for the transcription of MTHFD2 (42). The transcriptional program of ATF4 in HCC and its roles in HCC metabolism will be further explored in the future.

Interestingly, serine and glycine synthesis results in the production of glutathione, a tripeptide of glycine, glutamate, and cysteine (43). It was thus expectedly reported that knockdown of

Figure 8. Knockdown of MTHFD1L suppressed HCC growth and sensitized HCC cells to sorafenib treatment in vivo. (A) Luciferase-labeled MHCC97L-NTC, -shML-00, and -shML-99 cells were orthotopically injected into nude mice (n = 6 mice per experimental group) and allowed to grow for 45 days. Left: Bioluminescent image of mice implanted with different stable cells. Middle: Representative picture of orthotopic xenografts. Right: Quantification of tumor size. (B) Lung tissues were removed from mice of the orthotopic liver implantation model for Xenogen imaging. Left: Bioluminescent image of lung tissues. Right: Quantification of luciferase intensities of HCC cells in lung tissues. (C) H&E staining of the orthotopic tumors showing HCC-liver boundaries as indicated by arrows. Necrotic areas are represented by asterisks. (D) Growth curves of subcutaneous xenografts derived from MHCC97L-NTC and -shML-99 cells in nude mice that were administered vehicle control (Ctrl) or 30 mg/kg/d sorafenib (Sor) (n = 6 mice per experimental group). (E) Representative pictures of subcutaneous xenografts. (F) Quantification of tumor mass. Error bars indicate mean ± SEM. **P < 0.01, ***P < 0.001 vs. NTC, Ctrl-NTC, or as indicated. 1-way ANOVA. A and E: scale bar, 1 cm; C: scale bar, 100 μm.
PSPH in HCC cells reduced glutathione production, which consequently induced oxidative stress (40). Our current study indicated that this elevation of oxidative stress might be related to the decline of serine entering the folate cycle, which would otherwise produce NADPH directly. Interestingly, the final and rate-limiting enzyme of serine biosynthesis, PSPH, was significantly upregulated in human HCC (40). These reports echo in harmony with our findings of MTHFD1L overexpression in HCC patients, suggesting that 1-carbon metabolism provides metabolic and survival advantages to HCC cells.

Our study provides evidence that MTHFD1L was regulated by the NTC-1 Mouse Tumors growth fronts

mutations affect MTHFD1L expression and confer resistance to oxidative stress on HCC cells are also awaited.

Apart from NADPH, the folate cycle generates purine and pyrimidine; however, reduction of nucleotides in MTHFD1L-knockdown HCC cells was not observed, despite a significant decrease in cancer growth. This is similar to our previous observation in PPP blockade (6). PPP is connected to glycolysis and is a major pathway that produces NADPH and ribose 5-phosphate (RSP), the backbone of DNA. Suppression of PPP in HCC through inhibition of transketolase reduced NADPH with no significant reduction in RSP but strongly inhibited HCC growth (6). Our previous study together with this current one strongly supports the notion that cancer cells have greater demands for antioxidants than building blocks to support primary cancer growth. A worthwhile study recently demonstrated that the folate cycle allowed melanoma cells to survive within the circulation and metastasize distantly (25). Our orthotopic liver implantation model has shown that the knockdown of MTHFD1L prominently reduced lung metastasis. However, it is unclear whether it was a secondary response due to reduced primary tumor growth. Metastatic efficiency of cancer cells could be further evaluated by tail-vein or splenic injection in the future.

Recently, Ducker et al. elegantly demonstrated that cells would compensate for the deficiency in the mitochondrial folate pathway by reversing the cytosolic 1C flux, suggesting flexibilities between the mitochondrial and cytosolic compartments of the folate cycle (24). Ducker et al. showed that blocking the mitochondrial folate pathway by knocking out MTHFD2, MTHFD1L, or SHMT2 using the CRISPR-Cas9 genome editing approach in cells inhibited the generation of 10-CHO-THF, making cells dependent on SHMT1 for 1C unit production. They further showed that blocking SHMT1 and MTHFD2 together could completely retard colorectal cancer growth. This important study provided an explanation as to why MTHFD1L knockdown or knockout alone could not achieve full HCC growth inhibition, as only the mitochondrial compartment is blocked. This might also explain why the effects of knockout are not as dramatic as those of knockdown, because MTHFD1L-knockout cells might potentially be even more dependent on the cytoplasmic compartment than MTHFD1L-knockdown cells. A point worth mentioning is that NADPH from the mitochondrial compartment of the folate cycle is mainly produced by ALDH1L2, which competes with MTHFD1L for 10-CHO-THF. However, MTHFD1L is required for the production of formate, which could pass through the mitochondrial membrane. We further interrogated the ratios of these 2 enzymes in nontumorous and HCC tissues from the TCGA database. We found the MTHFD1L/ALDH1L2 ratio elevated in HCC (Supplemental Figure 8), suggesting that more 10-CHO-THF might be used by MTHFD1L to generate formate, which could sustain the continuity of the cytoplasmic compartment of the folate cycle in HCC. Another interesting point to note in the mitochondrial compartment of the folate cycle is that MTHFD2 and MTHFD2L compete for CH3-THF to make NADH and NADPH, respectively. TCGA data revealed that the mean values of the mRNA expression levels of MTHFD2 and MTHFD2L in HCC were 143.10 and 156.70, respectively (data not shown), suggesting that both enzymes are robustly expressed and both NADH and NADPH are required for HCC growth. The competi-
It was also shown that administration of the antioxidant NAC promoted melanoma cell metastasis (25). However, the extent and stage of diseases at which dietary folate or other antioxidant intakes are deemed harmful to human health remain unclear.

On the other hand, it has become apparent that antioxidant-producing pathways are attractive therapeutic targets for cancer cells given their increased reliance on antioxidants. Recently, an elegant study showed that combined usage of glutathione and thioredoxin inhibitors could efficiently block cancer initiation and growth in breast cancer model (5). Our current study has unequivocally showed that the inhibition of the folate cycle rendered cancer cells more sensitive to treatment with sorafenib, treatment between MTHFD1L and ALDH1L2 as well as MTHFD2 and MTHFD2L in the folate cycle will be an exciting avenue to be investigated.

The human body cannot synthesize folate de novo; thus folate must be taken up from diets. Dietary folate has long been advocated as having anticancer effects. Earlier epidemiological studies showed that dietary folate reduced the risk of several cancers, including breast and colorectal cancer (46, 47). These earlier studies were coherent with the traditional belief that ROS are protumorigenic. This long-standing concept, however, has been shaken by our renewed attention and expanding knowledge on cancer metabolism. A recent study showed that diet supplemented with antioxidant vitamin E or NAC promoted melanoma cell metastasis (25). However, the extent and stage of diseases at which dietary folate or other antioxidant intakes are deemed harmful to human health remain unclear. On the other hand, it has become apparent that antioxidant-producing pathways are attractive therapeutic targets for cancer cells given their increased reliance on antioxidants. Recently, an elegant study showed that combined usage of glutathione and thioredoxin inhibitors could efficiently block cancer initiation and growth in breast cancer model (5). Our current study has unequivocally showed that the inhibition of the folate cycle rendered cancer cells more sensitive to treatment with sorafenib, and NAC.
the only FDA-approved targeted therapeutic agent for advanced HCC patients. As we show that MTHFD1L is overexpressed in multiple solid cancers, it will be appealing to investigate whether folate inhibitors could be used in combination with other existing therapies in other cancer types. As we begin to understand more about the metabolic vulnerabilities in cancer, development of more precise inhibitors that specifically target the associated molecules is under way.

Methods
Clinicopathological correlation analysis and survival analysis. Clinicopathological features of human HCC were correlated with MTHFD1L expression in clinical specimens. Correlation of the features, including cellular differentiation, direct liver invasion, hepatitis B surface antigen, tumor encapsulation, tumor microsatellite formation, tumor size, and venous invasion, was performed using SPSS 20.0 software (IBM Corp.). Pathological tumor node metastasis (pTNM) tumor staging was analyzed and graded by a pathologist. Demographics of HCC patients from our center are summarized in Supplemental Table 1. Patient survival data of 442 HCC patients were obtained from TCGA cBioPortal. MTHFD1L expression in HCC patients was defined as high if the Z score was greater than 1, or otherwise low. Survival analysis was determined by Kaplan-Meier followed by log-rank test.

Cell culture. HCC cell lines MHC97L, PLC/PRF/5, Huh7, HepG2, Hep3B, and Hepa 1-6 were used. MHC97L was a gift from Z.Y. Yang (Fudan University of Shanghai, Shanghai, China). HepG2, Hep3B, and Hepa 1-6 were obtained from American Type Culture Collection (ATCC) and were cultured in DMEM–high glucose (DMEM-HG) media supplemented with sodium pyruvate, unless indicated. PLC/PRF/5 and Huh7, both obtained from ATCC, were cultured with DMEM-HG, unless indicated. All culture media were supplemented with 10% FBS (all reagents from Gibco).

RNA extraction, reverse transcription PCR, and quantitative real-time PCR. Total RNA was extracted from clinical specimens that were snap-frozen using liquid nitrogen prior to storage at −80°C, and HCC cell lines using the TRIzol reagent (Life Technologies). cDNA was synthesized from purified RNA samples by reverse transcription using the GeneAmp PCR Reagent Kit (Applied Biosystems). Quantitative real-time PCR amplifications of MTHFD1L and the internal control 18S were performed using the TaqMan Gene Expression Assay (Applied Biosystems) for clinical specimens and using the SYBR Green qPCR Master Mix (Applied Biosystems) with corresponding primers (Supplemental Table 2) for HCC cell lines.

Transcriptome sequencing. Transcriptome sequencing was performed using 16 pairs of human HCC tissues and their adjacent nontumorous liver tissues. The poly(A)+ mRNA library was prepared using the TruSeq Stranded mRNA Sample Prep Kit (Illumina). Using Illumina HiSeq2000 (Axeq Technologies), 100-bp paired-end sequencing was performed. Subsequent data analysis was performed by the TopHat-Cufflinks pipeline, and the resulting values were indicated by FPKM (fragments per kilobase of transcript sequence per million mapped reads).

The Cancer Genome Atlas. Transcriptome sequencing data using 50 pairs of human HCC tissues and their adjacent nontumorous liver tissues as well as other solid cancers including esophageal cancer, gastric adenocarcinoma, bladder cancer, lung adenocarcinoma, breast cancer, colon adenocarcinoma, kidney renal cell carcinoma, and prostate cancer were retrieved from The Cancer Genome Atlas (TCGA) via the Broad GDAC Firehose (Broad Institute). Only the available paired samples with both solid tumors and nontumorous counterparts were included in the comparison study. Cases without matched nontumorous tissues were excluded for this analysis. Comparisons were done with paired t test.

ChIP assay. ChIP assay was performed as we previously described (49). In brief, cells were fixed with 3.7% formalin (vol/vol) and then sonicated. Sheared DNA was incubated with antibodies against NRF2 (anti-rabbit, catalog ab62352, Abcam) or IgG control (anti-rabbit, catalog sc-207, Santa Cruz Biotechnology). DNA-protein-antibody complexes were incubated with Protein A/Salmon Sperm DNA Agarose Beads (Thermo Fisher Scientific). Beads were washed sequentially with gradients of salt buffer and eluted in 1% SDS/NaHCO3. ChIP DNA was analyzed with primers flanking the putative AREs. Primer sequences are provided in Supplemental Table 2.

Stable HCC cell establishment. HCC cell lines with stable knockdowns were produced using a lentiviral-mediated approach as previously described (49–51). In short, pLKO.1-puro vectors encompassing shRNAs targeting MTHFD1L (shMTHFD1L), NRF2 (shNRF2), or a nontarget control were stably transfected into HCC cell lines. Puromycin was used for the selection of HCC cells with stable expression of shRNAs. MTHFD1L- and NRF2-overexpressing cell lines were generated using CRISPR-dCas9 Synergistic Activation Mediator (SAM) system as previously described (52). dCas9–VP64, MS2-p65-HSF1, and single guide RNAs (sgRNAs) targeting the promoters of MTHFD1L were transfected into MHC97L cells with sequential lentiviral infections. Zeocin was used for the selection of HCC cells with stable expression of sgRNAs for the CRISPR-dCas9 SAM system. For MTHFD1L-knockout cell establishment, Cas9 and sgRNA were introduced into MHC97L and PLC cells through a lentiviral-mediated approach as previously described (53). Puromycin was used for the selection of HCC cells with stable expression of the sgRNAs for the CRISPR-Cas9 gene editing (KO) system. Sequences of all sgRNAs and shRNAs are provided in Supplemental Table 3.

Western blotting. Protein extraction was performed on clinical HCC specimens snap-frozen using liquid nitrogen prior to storage at −80°C, and on HCC cells using the radioimmunoprecipitation assay (RIPA) buffer supplemented with complete protease inhibitor (Roche) and PhosSTOP phosphatase inhibitor cocktails (Roche). Equal volumes of protein lysates were separated using 10% (vol/vol) SDS-PAGE, and transferred onto PVDF membranes (GE Healthcare). For immunoblotting, antibodies against MTHFD1L (anti-rabbit, catalog HPA029041, Abcam and Atlas Antibodies), NDUF4A4 (anti-rabbit, catalog ab129752, Abcam), NRF2 (anti-rabbit, catalog 12721, Cell Signaling Technology), and β-actin (anti-mouse, catalog A5316, Sigma-Aldrich) were used.

Cell proliferation assays. Cell proliferation rates were measured using 2 different assays: cell counting and 5-bromo-2′-deoxyuridine (BrdU) colorimetric (Roche) assay. For proliferation rates determined by cell counting, 2 × 104 cells per well were plated onto 12-well culture plates. Cells were trypsinized and counted using the Z1 Particle Counter (Beckman Coulter) 24 hours after plating of cells, daily for 4 days. For proliferation rates determined by BrdU assay, 1 × 104 cells per well were plated onto 96-well culture plates. BrdU labeling and colorimetric measurements were performed 24 hours after plating of cells according to the manufacturer’s instructions (Roche).
ROS, NADPH, and 8-OH-dG measurements. Intracellular ROS levels were measured in equal amounts of HCC cells plated into 6-well dishes. Cells were trypsinized and washed with PBS before staining with 2 μmol/l chloromethyl-20,70-dichlorodihydrofluorescein diacetate (CM-H,DCFDA) oxidative stress indicator (Life Technologies) and analyzed using the FACS Canto II Analyzer (BD Biosciences) flow cytometer. Results were analyzed using FlowJo software (FlowJo).

Intracellular NADPH/NADP⁺ ratios were determined in HCC cells using the NADP/NADPH Quantification Colorimetric Kit (BioVision) according to the manufacturer’s instructions. Briefly, equal amounts of plated HCC cells on 6-well dishes were trypsinized and subjected to extraction by 2 freeze/thaw cycles using the Extraction Buffer. Portions of the extracted samples were heated at 60°C for 30 minutes to allow for NADP decomposition while the other portion was left on ice (unheated). Both portions of the sample then underwent NADP cycling through incubation with the Cycling Buffer for 5 minutes before reaction development with the NADPH Developer. Intensities of the NADPH and NAPD signals were measured with a plate reader at an OD of 450 nm. The NADPH/NADP⁺ ratio was calculated as: (intensity of heated samples) / (intensity of unheated samples – intensity of heated samples). For 8-OH-dG assay, 5 × 10⁴ MHCC97L-NTC or -shMTHFD1L cells were seeded on 12-well plates, and DNA was extracted by phenol chloroform. Seven micrograms of DNA was added into an 8-OH-dG antibody precoated ELISA plate (Abcam) and incubated at room temperature for 1 hour. The ELISA plate was subsequently washed and developed with substrates following the manufacturer’s protocol (Abcam).

Oxygen consumption rate analysis. Oxygen consumption was measured by XFp Cell Mito Stress Test according to the manufacturer’s protocol (Seahorse Bioscience). In brief, MHCC97L-NTC or -shMTHFD1L cells were seeded onto microplates at 50% confluence. One micromolar oligomycin, 0.125–2 μM FCCP, and 0.5 μM rotenone and antimycin A were injected into wells at the indicated time points, and oxygen content was measured by XFp Analyzer (Seahorse Bioscience).

Cell cycle analysis. The analysis of cell cycle distributions was performed using propidium iodide (PI) stain (Calbiochem) subjected to flow cytometric analysis. Briefly, cells were treated with nocodazole (200 ng/ml) for 16 hours for synchronization in the G1 phase of the cell cycle. Nocodazole was removed from the cells after synchronization for 9 hours before harvesting for fixation using 75% (vol/vol) ethanol for 1 hour. Cells were stained with 50 μg/ml PI for 30 minutes under incubation before analysis using the FACS Canto II Analyzer (BD Biosciences).

Cell apoptosis analysis. Cells were cultured in serum-free medium for 24 hours before trypsinization and subsequently resuspended in Annexin V binding buffer (BD Biosciences) with annexin V–FITC (MBL International) and PI (BD Biosciences) for staining at room temperature for 15 minutes according to the manufacturer’s instructions. The percentage of cell apoptosis for each sample was analyzed with flow cytometry.

Metabolomics. MHCC97N-NTC or -shMTHFD1L cells were washed with 5% (wt/wt) mannitol and scraped with methanol in the presence of 10 μM of internal control solution comprising compound C1 with m/z at 182.048 and compound A1 with m/z at 231.070 (Human Metabolome Technologies). Supernatants were filtered by centrifuge filter unit and evaporated by centrifugation. Extracted intracellular metabolites were analyzed by CE-TOFMS by Human Metabolome Technologies.

Animal experiments. Animal experiments were performed on 6- to 8-week-old male BALB/cAnN-nu (nude) mice. For the orthotopic tumor model, 1 × 10⁶ MHCC97L cells, luciferase-labeled, were resuspended in 100% Matrigel (BD Biosciences) and injected into the left lobes of the livers of the nude mice. Drug administration began 1 week after inoculation. At 6 weeks (42 days) after inoculation, tumor-bearing mice were administered 100 mg/kg D-Luciferin (PerkinElmer) via i.p. injections for bioluminescence imaging using the Xenogen IVIS 100 Imaging System (Xenogen). Livers and lungs were also harvested for ex vivo imaging as well as 10% formalin fixation followed by H&E staining for histological analysis. For the syngeneic model, 4 × 10⁶ Hepa 1-6 cells were resuspended in 100 μl PBS and injected s.c. onto either flank of the nude mice. Tumor volumes were measured using an electronic caliper and calculated as mentioned above. Drug administration began 1 week after inoculation. For the patient-derived tumor xenograft model, 1 × 10⁶ cells from an HCC patient (PY003) were resuspended in 100% Matrigel and injected s.c. into nude mice. Drug administration began 11 days after inoculation. Tumor volumes were measured using an electronic caliper and calculated as mentioned above.

Pharmacological studies. HCC cells were treated with pharmacological agents in vitro for cell proliferation assay, ROS measurement, cell cycle analysis, and cell apoptosis experiments. Sorafenib (LC Laboratories) was dissolved in DMSO, while MTX (Sigma-Aldrich) was dissolved in H₂O and 0.5% 4 M NaOH, and glutathione reduced ethyl ester (GSH-EE) (Cayman Chemical), l-glutathione reduced (GSH), and N-acetyl-l-cysteine (NAC) (both from Sigma-Aldrich) were all dissolved in H₂O. Sorafenib and MTX were also administered via oral gavage and i.p. injections, respectively, in vivo daily.

Oil Red O staining. Staining of neutral triglyceride and lipids was performed on cultured cells and frozen sections from livers of HCC-bearing mice using Oil Red O (Sigma-Aldrich) dissolved in isopropanol. To stain cultured cells, 1 × 10⁶ MHCC97L-NTC or -shM cells were seeded onto 6-well plates. Plates were fixed with 10% formalin before staining with Oil Red O working solution diluted with distilled water. After removal of the stain and several washes with distilled water, Oil Red O dye on the dried cells was eluted with 100% isopropanol. Relative amounts of neutral triglyceride and lipids were determined by OD measurements at 500 nm with 100% isopropanol as blank. To stain for neutral triglyceride and lipids from livers of HCC-bearing mice, frozen sections were air-dried and fixed in formalin. After rinsing with 60% isopropanol, frozen sections were stained in Oil Red O before another rinse with 60% isopropanol. Sections were stained with hematoxylin, rinsed with hard water, and finally mounted in aqueous mountant for imaging and microscope analysis.

Statistics. All statistical analyses were performed using GraphPad Prism 5.0 software (GraphPad Software Inc.) by either 1-way ANOVA with Bonferroni’s correction, Student’s t test, or Wilcoxon signed-rank test. All functional assay experiments are representations of at least 3 independent experiments expressed as mean ± SEM. Statistical significance was considered with a P value less than 0.05.
**Study approval.** The use of clinical HCC tumor samples and their adjacent nontumorous liver tissues in the study was approved by the Institutional Review Board of the University of Hong Kong and the Hospital Authority of Hong Kong (HKU/HA HKW IRB; ref. no. UW 09-158). The clinical specimens were obtained from patients admitted to Queen Mary Hospital. Signed consent forms were obtained from patients as acknowledgment prior to the collection and usage of resected tissues. All experimental procedures performed on animals were approved by the Committee on the Use of Live Animals in Teaching and Research of the University of Hong Kong and conformed to the Animals (Control of Experiments) Ordinance of Hong Kong. All animal experiments were performed under the UK Co-ordinating Committee on Cancer Research PMID: 9459138 Guidelines for the Welfare of Animals in Experimental Neoplasia to ensure minimal suffering during the experimental procedures (54).

**Author contributions**

DL, IOLN, and CCLW designed the studies. DL and CCLW wrote the paper. DL, IMJX, DKCC, RKHL, APWT, LLI, CTL, FHCT, LLW, CYKC, CMW, and CCLW performed the experiments. CMW and CCLW performed statistical analysis.
