ABSTRACT

We present an X-ray spectro-polarimetric analysis of the bright Seyfert galaxy IC 4329A. The *Imaging X-ray Polarimetry Explorer (IXPE)* observed the source for ~ 500 ks, supported by *XMM-Newton* (~ 60 ks) and *NuSTAR* (~ 80 ks) exposures. We detect polarization in the 2–8 keV band with 2.97σ confidence. We report a polarization degree of 3.3 ± 1.1 per cent and a polarization angle of $78^\circ \pm 10^\circ$ (errors are 1σ confidence). The X-ray polarization is consistent with being aligned with the radio jet, albeit partially due to large uncertainties on the radio position angle. We jointly fit the spectra from the three observatories to constrain the presence of a relativistic reflection component. From this, we obtain constraints on the inclination angle to the inner disc ($< 39^\circ$ at 99 per cent confidence) and the disc inner radius (< 11 gravitational radii at 99 per cent confidence), although we note that modelling systematics in practice add to the quoted statistical error. Our spectropolarimetric modelling indicates that the 2–8 keV polarization is consistent with being dominated by emission directly observed from the X-ray corona, but the polarization of the reflection component is completely unconstrained. Our constraints on viewer inclination and polarization degree tentatively favour more asymmetric, possibly out-flowing, coronal geometries that produce more highly polarized emission, but the coronal geometry is unconstrained at the 3σ level.

Key words: polarization – galaxies: active – galaxies: individual: IC 4329A – galaxies: Seyfert.

1 INTRODUCTION

Active galactic nuclei (AGNs) are powered by accretion of material from the host galaxy on to the central supermassive black hole.

An optically thick, geometrically thin disc that radiates a multi-temperature blackbody spectrum peaking in the ultraviolet (UV) is thought to be present (Novikov & Thorne 1973; Shakura & Sunyaev 1973), whereas the X-ray spectrum is typically dominated by a power law with high-energy cut-off. The power-law component is thought to result from Compton up-scattering of disc seed photons by a hot thermal population of electrons in a cloud of moderate optical

* E-mail: adam.ingram@newcastle.ac.uk

depth ($\tau \sim 0.5\text{--}3$) located close to the hole (Thorne & Price 1975; Sunyaev & Truemper 1979), commonly referred to as the *corona*. The geometry and physical nature of the corona are still debated (e.g. Poutanen, Veledina & Zdziarski 2018). Proposed geometries include a patchy layer sandwiching the disc (Galeev, Rosner & Vaiana 1979; Haardt, Maraschi & Ghisellini 1994; Stern et al. 1995), a large scale height accretion flow that forms inside of a truncated disc (the truncated disc model; e.g. Eardley, Lightman & Shapiro 1975; Veledina, Vurm & Poutanen 2011), and a compact or vertically extended region at the base of the outflowing jet (Martocchia & Matt 1996; Henri & Petrucci 1997; Miniutti et al. 2003; Markoff, Nowak & Wilms 2005). Essentially all of these models can reproduce the observed X-ray spectrum, and so a new diagnostic is required to break the impasse.

Modelling of the *reflection* spectrum that results from coronal X-rays irradiating the disc and being re-processed has provided hints. The emergent spectrum includes a Compton hump at $\sim 20\text{--}30$ keV and an iron emission line at ~ 6.4 keV (Matt, Perola & Piro 1991) that is broadened and skewed by disc orbital motion and gravitational redshift (Fabian et al. 1989). The line profile depends on the disc inclination and inner radius as well as the radial dependence of illuminating intensity (the *emissivity profile*), which in turn depends on the geometry of the corona (e.g. size and radial/vertical extent). Studies that parametrize the emissivity profile as a broken power law often infer very centrally peaked irradiation (emissivity of $\epsilon(r) \propto r^{-q}$, where $q \gtrsim 7$), implying that the corona is very compact (e.g. Reynolds 2021). However, considering for example a radially stratified corona approximated by two regions each with their own power-law index and reflection spectrum can produce fits as good as those considering a single compact corona (Basak et al. 2017).

Additionally including timing information can in principle break degeneracies. Features consistent with reverberation lags – caused by reflected photons taking a longer path than directly observed photons – have been detected for ~ 25 AGNs (Kara et al. 2016). Modelling of these reverberation features provides a means to measure black hole mass, but this measurement is likely dependent on the unknown coronal shape (Mastroserio, Ingram & van der Klis 2020).

The *Imaging X-ray Polarimetry Explorer (IXPE)*, which was launched on 2021 December 9, provides the hitherto inaccessible diagnostic of X-ray polarization. The polarization of the corona, which is determined by the physics of Compton scattering, informs on its degree of asymmetry and its orientation on the sky (see Fig. 1). The more asymmetric the projection of the corona on the sky is, the more polarized we measure it to be (e.g. Schnittman & Krolik 2010). Therefore, for example, the polarization of a torus-shaped corona is greater for a smaller aspect ratio and a more edge-on viewing angle. The polarization is expected to align with the minor axis of the corona, such that a horizontally extended corona will be vertically polarized. As for reflection, the iron line should only be very weakly polarized,¹ whereas the reflection continuum (i.e. everything except for the fluorescence lines) can be highly polarized (e.g. Matt 1993; Poutanen, Nagendra & Svensson 1996; Dovčiak et al. 2011).

IXPE is sensitive to 2–8 keV photons, and has so far observed four radio-quiet AGNs: the Circinus galaxy (Ursini et al. 2023), MCG-05-23-16 (Marinucci et al. 2022), NGC 4151 (Gianoli et al. 2023) and, most recently IC 4329A. IC 4329A (redshift $z = 0.0161$; Willmer et al. 1991) is a Seyfert Type 1.2 galaxy (Véron-Cetty & Véron 2006), meaning that its optical spectrum includes both broad

and narrow emission lines and its X-ray spectrum is relatively unobscured. This indicates in the unification scheme (Urry & Padovani 1995) that the inclination angle is small enough for our sight line to the supermassive black hole to not be blocked by the dusty torus, such that we see X-rays directly from the accretion flow and broad optical lines from gas rapidly orbiting the black hole (the broad-line region). A recent optical reverberation campaign (Bentz et al. 2023) further backed up this hypothesis and provided a black hole mass measurement of $M \approx 7 \times 10^7 M_{\odot}$, broadly consistent with earlier estimates (e.g. González-Martín & Vaughan 2012). An X-ray reverberation feature consistent with this mass has been observed from the source (Kara et al. 2016). IC 4329A was selected for an *IXPE* observation primarily because it is one of the brightest AGN in the X-ray sky, with a 2–10 keV flux in the range $F_{2-10} \sim (0.1\text{--}1.8) \times 10^{-10} \text{ erg s}^{-1} \text{ cm}^{-2}$ (e.g. Beckmann et al. 2006). Optical images show that we view the host galaxy edge-on, with the dust lane associated with the galaxy’s spiral arms cutting across our view of the nucleus (Martin et al. 1982; Mehdipour & Costantini 2018; Bentz et al. 2023). This implies that the AGN torus is misaligned with the galaxy rotation axis, which could be due to a past interaction with the nearby giant lenticular galaxy IC 4329, although we note that such a misalignment is apparently fairly common (e.g. Schmitt et al. 1997; Nagar & Wilson 1999; Middleton et al. 2016).

Here, we present the results of an observing campaign on IC 4329A utilizing *IXPE* as well as the *X-ray Multi-Mirror Mission (XMM-Newton)* and the *Nuclear Spectroscopic Telescope ARray (NuSTAR)*. In Section 2, we detail our data reduction procedure. In Section 3, we present our polarimetric analysis as well as spectral and spectropolarimetric fits. In Section 4, we discuss our results in the context of Comptonization models of polarization and multiwavelength observations of the system, and we summarize our results in Section 5.

2 OBSERVATIONS AND DATA REDUCTION

IXPE observed IC 4329A on 2023 January 5–15 (OBSID 01003601) for a useful exposure time of 458 ks. During this observation, *XMM-Newton* also observed the source on January 11–12 (OBSID 0890670201) for an exposure time of 62 ks, and *NuSTAR* observed it on January 11–13 (OBSID 60701015002) for an exposure of 82 ks. The light curves of all three of these observations are presented in Fig. 2. The following subsections detail the data reduction procedure we employed for the three observatories. Throughout, we make use of FTOOLS from the HEASOFT package (v6.31.1).

2.1 IXPE

We downloaded cleaned level 2 event files, taken by the three Gas Pixel Detectors (Costa et al. 2001), from the High Energy Astrophysics Science Archive Research Center,² that had been calibrated with the standard pipeline. We use the public tool IXPEOBSSIM (v30.0.0; Baldini et al. 2022) to extract Stokes parameters individually for the three detector units (DUs), employing the most recent *IXPE* calibration data base files (CALDB 20221020). We employ a circular source region centred on the source with radius 60 arcsec. The background region is an annulus, also centred on the source, with inner and outer radii of 150 and 300 arcsec, respectively. These regions are chosen such that the source region captures

¹ Fluorescence photons are initially unpolarized, but can pick up a small degree of polarization via scatterings as they propagate out of the disc atmosphere.

Figure 1. Schematic diagram demonstrating the basic physics governing X-ray polarization. The adopted coordinate system is shown, with the observer’s sight line being placed in the positive x -direction. The corona and disc are represented, respectively, by the blue and red regions. The electric field oscillation corresponding to photons before and after a Compton scattering event with an electron (black circles) are colour-coded red and blue, respectively. The trajectory of a photon after a scattering is most likely to be in the plane perpendicular to its electric polarization vector. Therefore, photons that reach the observer vertically polarized (i.e. in the z -direction) were most likely travelling in the x - y plane just before their final scattering, whereas photons that reach the observer horizontally polarized (i.e. in the y -direction) were most likely travelling in the x - z plane just before their final scattering. This means that a corona extended in the x - y plane will overall be vertically polarized because more photons were travelling in the x - y plane before their final scattering due to the higher scattering optical depth in this plane. Similarly, photons from the corona that scatter off free electrons in the disc (black line) become polarized perpendicular to their initial direction of travel (ignoring relativistic effects). This results in the Compton hump being approximately polarized in the direction of the disc normal.

Figure 2. Light curves (counts per second) of IC 4329A as observed by *XMM-Newton* EPIC-pn (2–10 keV, 100 s time bins, red), *NuSTAR* (3–10 keV, 200 s time bins, blue), and *IXPE* (2–8 keV, 1 ks time bins black). For *NuSTAR* and *IXPE*, separate detectors have been summed. Time is represented as days in 2023 January, such that 10 is midnight on January 10.

maximal source photons and the background region is as large as possible whilst avoiding source contamination.

We employ two methods to determine the polarization in the 2–8 keV energy band. First is the `pcube` algorithm, which sums Stokes parameters of individual events within the extraction region and specified energy range. The polarization degree (PD) relates to the summed Stokes parameters I , Q , and U as $p = \sqrt{(Q/I)^2 + (U/I)^2}$, and the polarization angle (PA) is $\psi = (1/2)\arctan(U/Q)$ (i.e. in this notation, Q and U are corrected for the modulation factor). Uncertainties are calculated using standard formulae (Muleri 2022). We extract summed Stokes parameters separately from the source and background regions for each DU. Taking advantage of the linear properties of Stokes parameters, we combine DUs by summing Stokes parameters and account for background by subtracting the background region Stokes parameters from the source region Stokes parameters. We combine uncertainties by summing in quadrature.

The second method is to extract I , Q , and U source and background spectra for each DU using the PHA algorithm. We group the Q and U spectra into energy bins 0.2 keV wide, and for I instead employ the native energy bins of width 0.04 keV. We extract I , Q , and U spectra employing both ‘weighted’ and ‘unweighted’ methods. A weighted analysis gives extra weight to events with better characterised photoelectron tracks (Di Marco et al. 2022), whereas this extra information is ignored in an unweighted analysis. Finally,

we also extract weighted I , Q , and U spectra from event files filtered using the background rejection method of Di Marco et al. (2023).

Using XSPEC v12.12.1 (Arnaud 1996), we fit the model

$$\text{TBabs} \times \text{const} \times \text{polconst} \times \text{po}, \quad (1)$$

simultaneously to I , Q , and U spectra. Here, TBabs (Wilms, Allen & McCray 2000) represents line-of-sight absorption, for which we fix the hydrogen column density to $N_{\text{H}} = 4.1 \times 10^{20} \text{ cm}^{-2}$ (HI4PI Collaboration et al. 2016). The constant `const` accounts for cross-calibration between different DUs. It is therefore tied between I , Q , and U of the same DU, but allowed to differ between DUs. `po` is simply a power law (specific photon flux $\propto E^{-\Gamma}$). `polconst` imparts a constant (i.e. independent of energy) PD and PA to the model it operates on. We fit the above model simultaneously to all *IXPE* DUs, leaving free the power-law index and normalization, the calibration constants, and the PD and PA. Although we consider the three DUs separately in the fits, we combine them in plots for clarity.

2.2 XMM-Newton

XMM-Newton observed the source with the EPIC CCD cameras: the pn (Strüder et al. 2001) and the two MOS (Turner et al. 2001), operated in small window and medium filter mode. Data from the MOS detectors are not included in our analysis due to pile-up. The data from the pn camera show no significant pile-up as indicated by the `epatplot` output. The extraction radii and the optimal time cuts for flaring particle background were computed with SAS 20 (Gabriel et al. 2004), via an iterative process which leads to the maximization of the signal-to-noise ratio (SNR) in the 0.5–10 keV energy band, similar to the approach described in Piconcelli et al. (2004). The resulting optimal extraction radii for the source and the background spectra are 40 and 50 arcsec, respectively. The net exposure time for the pn time-averaged spectrum is 61.7 ks. The keyword `applyabsfluxcorr = yes` was applied in the `arfgen` task to correct the pn effective area, removing residuals between simultaneous *XMM-Newton* pn and *NuSTAR* spectra.

2.3 NuSTAR

NuSTAR (Harrison et al. 2013) observed the source with its two co-aligned X-ray telescopes with corresponding Focal Plane Module A (FPMA) and B (FPMB). The Level 1 data products were processed with the *NuSTAR* Data Analysis Software (NuSTARDAS) package (v. 2.1.2). Cleaned event files (level 2 data products) were

Figure 3. Constraints on the PD and PA (measured east of north) in the 2–8 keV band. Contours at 68, 90, and 99 per cent confidence levels are shown. Blue lines result from an unweighted analysis with the `pcube` algorithm. Block colours result from a weighted spectropolarimetric analysis within XSPEC that additionally makes use of the new background rejection method. We see that the weighted analysis provides consistent but more tightly constrained results.

produced and calibrated using standard filtering criteria with the `nupipeline` task and the calibration files available in the *NuSTAR* calibration data base (CALDB 20220510). Extraction radii for the source and background spectra were 40 and 60 arcsec, FPMA spectra were binned in order not to oversample the instrumental resolution more than a factor of 2.5 and to have an SNR greater than 5 in each spectral channel, the same energy binning was then applied to the FPMB spectra. The net observing times for the FPMA and the FPMB data sets are 82.4 and 81.5 ks, respectively. FPMA and FPMB spectra are considered separately for the purposes of spectral fitting, but are combined in plots for clarity.

3 RESULTS

3.1 X-ray polarization

We first measure the 2–8 keV polarization using the model-independent `pcube` algorithm on unweighted data. We find $p = 3.4 \pm 1.6$ per cent and $\psi = 64^\circ \pm 13^\circ$ (1σ uncertainties) for the PD and PA, and we plot statistical confidence contours in Fig. 3 (blue lines).

Currently, `pcube` does not feature the functionality to improve signal to noise by including event weights. Therefore to make use of a weighted analysis, we employ the alternative method of fitting weighted I , Q , and U spectra (produced utilizing the background rejection method) with a simple spectropolarimetric model (equation 1) within XSPEC. The best-fitting reduced χ^2 is $\chi^2/\text{d.o.f.} = 659/614$. This is an acceptable fit, although we note that a more complex model is required when we also include *XMM-Newton* and *NuSTAR* data (see the following two sections).

We find $p = 3.3 \pm 1.1$ per cent and $\psi = 78^\circ \pm 10^\circ$ (1σ errors for a single parameter of interest), and plot the confidence contours as block colours in Fig. 3. We see that, as expected, the results are consistent with the `pcube` method but with smaller uncertainties. The 99 per cent contour (representing 3σ for a two-dimensional distribution) still does not quite close, meaning that we fall just short of a 3σ detection of polarization. The formal confidence is 98.78 per cent, or 2.97σ . The 3σ upper limit on the PD is 6.2 per cent.

As a check, we also performed the fitting technique on unweighted data extracted without the background rejection method (Di Marco et al. 2023) and find results very close ($p = 3.7 \pm 1.2$ per cent, $\psi = 71^\circ \pm 10^\circ$) to those yielded by `pcube`. We also find that using or not using the background rejection method has no effect on the results within our chosen rounding convention.

An alternative way to assess the significance of a polarization measurement is to compare the measured PD to the minimum detectable polarization (MDP). This is the statistical upper limit on polarization that we would measure for an unpolarized source. Following convention (e.g. Mulieri 2022), we consider MDP_{99} , whereby the statistical upper limit is 99 per cent confidence. We calculate $\text{MDP}_{99} = 4.5$ per cent for the unweighted analysis and $\text{MDP}_{99} = 4.0$ for the weighted analysis. The measured polarization is thus lower than the MDP, meaning that the confidence with which we can rule out the source being unpolarized is less than 99 per cent (3σ). This is consistent with the 99 per cent confidence contours not fully closing in Fig. 3.

3.2 X-ray spectrum

We jointly fit the *IXPE*, *NuSTAR*, and *XMM-Newton* Stokes I spectra. We consider the usual energy ranges of 2–8 keV and 3–79 keV for *IXPE* and *NuSTAR*, respectively. For *XMM-Newton*, we consider the energy range of 2–10 keV, leaving the more involved treatment of ionized absorbers necessary to reproduce the soft X-rays (Mehdipour & Costantini 2018) to future work. We employ the following model, referred to hereafter as Model 1:

$$\text{mbpo} \times \text{zTBabs} \times \text{TBabs} \times [\text{nthComp} + \text{relxillCp} + \text{xillverCp}]. \quad (2)$$

Here, `nthcomp` (Zdziarski, Johnson & Magdziarz 1996; Życki, Done & Smith 1999) represents radiation produced by thermal Compton up-scattering in the corona, `relxillCp` (García et al. 2014) represents relativistic reflection from the accretion disc, and `xillverCp` (García et al. 2013) represents non-relativistic reflection from the distant molecular torus. `tbabs` (Wilms et al. 2000) represents line-of-sight absorption within our Galaxy (we continue to fix $N_{\text{H}} = 4.1 \times 10^{20} \text{ cm}^{-2}$), whereas `ztbabs` represents absorption within the host galaxy, perhaps including material local to the AGN. For this we leave, the column density as a free parameter. Finally, `mbpo` (Ingram et al. 2017) is required to circumvent cross-calibration discrepancies between the three observatories. It multiplies the total model by a broken power law with index $\Delta\Gamma_1$ for $E < E_{\text{br}}$ and $\Delta\Gamma_2$ for $E > E_{\text{br}}$. A single corrective power law (e.g. $\Delta\Gamma_1 = \Delta\Gamma_2$) has previously been required to jointly model *XMM-Newton* and *NuSTAR* data (Ingram et al. 2017), whereas a broken power law has been required to obtain agreement between *IXPE* and other observatories such as *NICER* and *NuSTAR* (Krawczynski et al. 2022). For $\Delta\Gamma_1 = \Delta\Gamma_2 = 0$, the model simply reduces to a multiplicative calibration constant. Note that dealing with cross-calibration in this way adjusts the *model* and not the data, such that a common set of

Table 1. The best-fitting Model 1 (equation 2) parameters from our joint spectral analysis.

Model 1			
zTBabs×TBabs×(nthcomp + relxillCp + xillverCp)			
Component	Parameter	Units	Value

	E_{br}	keV	$6.0^{+1.3}_{-0.8}$
	N		$0.65^{+0.02}_{-0.03}$

Note. Errors are 90 per cent confidence, and a \equiv symbol indicates that the parameter is fixed/hardwired. Reduced χ^2 is $\chi^2/\text{d.o.f.} = 1093/1047$. A gravitational radius is $r_{\text{g}} = GM/c^2$. The 3–79 keV NuSTAR FPMA flux is $F_{3-79} = 2.7 \times 10^{-10} \text{ erg s}^{-1} \text{ cm}^{-2}$, corresponding to isotropic luminosity $L_{3-79} = 1.5 \times 10^{44} \text{ erg s}^{-1}$ assuming a Hubble constant of $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. The 2–8 keV IXPE DU1 flux is $F_{2-8} = 5.3 \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2}$.

model parameters can be used to describe the source spectrum but discrepancies between observatories are preserved in plots.

We achieve a good fit with $\chi^2/\text{d.o.f.} = 1093/1047$. The best-fitting parameters are presented in Table 1. In Fig. 4, we plot the unfolded spectrum (a), the model spectrum with separate components (b) and the contributions to fit statistic χ (d). In our best-fitting model, ~ 66 per cent of the 2–8 keV photons are from the direct component, ~ 33 per cent are from the relativistic reflector, and ~ 1 per cent are from the distant reflector. All three components are required with high statistical significance. Fitting with only nthcomp yields $\chi^2/\text{d.o.f.} = 1794/1054$. Including the distant reflector reduces this

Figure 4. Spectral energy distribution for Model 1 (equation 2). (a) Best-fitting spectral model (black) with unfolded data. (b) Best-fitting model only (black) with individual components (grey). From top to bottom these are nthcomp, relxillCp, and xillverCp. (c) Unfolded Stokes Q (cyan circles) and U (magenta triangles) observed by IXPE with best-fitting model (black lines, top is U and bottom is Q). (d) Contributions to fit statistic χ . dN/dE is in units of photons $\text{cm}^{-2} \text{ s}^{-1} \text{ keV}^{-1}$.

to $\chi^2/\text{d.o.f.} = 1131/1051$, and finally also including the relativistic reflector yields the best-fitting model (5.1σ significance, p -value of 3.7×10^{-7} , according to an F -test). We calculate errors on our best-fitting model parameters by running a Markov Chain Monte Carlo (MCMC) simulation within XSPEC. We employ the Goodman & Weare (2010) algorithm with 256 walkers and a total length of 307 200 steps after a burn-in period of 19 200 steps.

The only free parameters of the nthcomp component are the photon index Γ , the electron temperature kT_e and the normalization norm. For computational convenience, we include nthcomp into our model via relxillCp with the reflection fraction parameter (refl_frac) set to zero. This returns the illuminating continuum (nthcomp) in exactly the same normalization as that used for the reflection calculation. This choice therefore makes it straight forward to interpret the reflection fraction parameter of the relativistic and distant reflection components. The seed photon temperature is hardwired to $kT_{\text{bb}} = 0.05 \text{ keV}$ in the xillverCp grid, which is appropriate for an AGN, for which the low energy break is expected to be beyond the low-energy bandpass of our observations. Our measured value of Γ agrees with previous studies (e.g. Brenneman et al. 2014a). Our inferred electron temperature broadly agrees with

Figure 5. Constraints on the inclination angle i and the disc inner radius r_{in} based on our Model 1 spectral fit. The 1, 2, and 3σ confidence contours are shown with black, red, and blue curves, respectively. The best fit is represented by a black cross.

Table 2. Coronal PD (p_{comp}) and PA (ψ_{comp}) inferred from our spectropolarimetric fits for different modelling assumptions.

Model	p_{comp} (per cent)	ψ_{comp} (deg)
(a) Model 1, $p_{\text{ref}} = 0$	5.0 ± 2.6	78 ± 15
(b) Model 2, $p_{\text{ref}} = 0$	3.4 ± 1.7	78 ± 15
(c) Model 2, $\psi_{\text{ref}} = \psi_{\text{comp}} + 90^\circ$	4.4 ± 1.9	78 ± 14
(d) Model 2, $\psi_{\text{ref}} = \psi_{\text{comp}}$	3.4 ± 1.7	78 ± 15

Note. Errors are 1σ . The confidence contours corresponding to each model are plotted in Fig. 7.

previous *NuSTAR* and *Suzaku* observations (Brenneman et al. 2014a, b).

For the relativistic reflector (`relxillCp`), we tie Γ , kT_e and norm to their `nthcomp` values, fix the reflection emissivity profile to $\epsilon(r) \propto r^{-3}$ and freeze the disc density to $n_e = 10^{15} \text{ cm}^{-3}$. We freeze the black hole spin parameter to its maximum value of $a = 0.998$ and leave the disc inner radius r_{in} free. This enables us to explore the widest possible range of r_{in} values without it becoming smaller than the innermost stable circular orbit (ISCO) during the fitting procedure. Although the spin itself does influence the model outputs via the photon geodesics, these are very subtle higher order effects. The other free parameters are inclination angle i , the logarithm of the ionization parameter $\log \xi$ (where ξ is in units of erg cm s^{-1} , and we take log to mean log to the base 10 throughout), the iron abundance relative to solar A_{Fe} , and the reflection fraction f_{ref} . We set the reflection fraction to a negative value within the model, meaning that the code outputs the reflected component only (conversely, a positive value returns the sum of direct and reflected components). Treating direct and reflected components separately in XSPEC will later allow us to assign different polarization properties to each of them. In the tables, we convert the reflection fraction back to a positive value. Low inclination and a small disc inner radius are preferred, but the contour plot in Fig. 5 shows that a wide range of values are acceptable within 3σ confidence. Our constraints are consistent with earlier analyses that used the less sophisticated `diskline` model

Table 3. The best-fitting Model 2 (equation 3) parameters from our joint spectral analysis.

Model 2 <code>zTBabs</code> × <code>TBabs</code> × (<code>cutoffpl</code> + <code>pexriv</code> + <code>laor</code> + <code>gauss</code>)			
Component	Parameter	Units	Value
<code>zTBabs</code>	N_{H}	10^{22} cm^{-2}	$0.52^{+0.05}_{-0.04}$
<code>TBabs</code>	N_{H}	10^{22} cm^{-2}	$\equiv 0.041$
<code>cutoffpl</code>	Γ		$1.74^{+0.02}_{-0.02}$
	E_{cut}	keV	395^{+194}_{-80}
	norm	10^{-2}	$2.14^{+0.07}_{-0.07}$
<code>pexriv</code>	f_{ref}		$0.22^{+0.06}_{-0.04}$
	ξ	erg cm s^{-1}	82^{+112}_{-62}
<code>laor</code>	E_{line}	keV	$6.26^{+0.01}_{-0.02}$
	i	deg	17^{+28}_{-15}
	a		$\equiv 0.998$
	r_{in}	r_{g}	$2.8^{+3.3}_{-1.4}$
	$\epsilon(r)$		$\equiv r^{-3}$
<code>gauss</code>	norm	10^{-5}	$5.0^{+3.2}_{-2.4}$
	norm	10^{-5}	$6.38^{+0.57}_{-0.86}$

Note. Errors are 90 per cent confidence. Reduced χ^2 is $\chi^2/\text{d.o.f.} = 1110/1047$. The `mbp0` cross-calibration parameters are consistent with their Model 1 values (Table 1). We allow the iron line centroid energy E_{line} to be a free parameter to circumvent the calibration discrepancies also encountered when fitting Model 1.

Figure 6. Best-fitting Model 2 spectrum (top) and residuals to *IXPE* (red), *NuSTAR* (blue), and *XMM-Newton* (green) data. Different lines represent the total model (black solid), cut-off power law (dotted), `pexriv` (dot-dashed), `laor` (solid), and the narrow Gaussian (dashed).

on *ASCA* data. Nandra et al. (1997) found $i < 24^\circ$ (1σ) whilst freezing $r_{\text{in}} = 6 r_{\text{g}}$, and Done, Madejski & Życki (2000) inferred a mildly truncated disc whilst achieving equally good fits for a range of different inclinations. For the distant reflector, we tie Γ , kT_e , norm and A_{Fe} to their `relxillCp` values, freeze $\log \xi = 0$ and leave f_{ref} as a free parameter.

The best-fitting values for $\log \xi$ and A_{Fe} are both rather large. Indeed, at $\log \xi \approx 4.4$ we may expect the disc to be overionized such that no features are present in the reflection spectrum. However,

Fig. 4(b) shows that a broad iron line and Compton hump can still be seen in the spectrum of the relativistic reflector (second grey line from the top), which occurs because the reflection features are boosted by the very high iron abundance. This combination of parameters is likely the result of the model mimicking some physics that we are not currently including (see Section 4 for a detailed discussion on this).

Throughout we fix the redshift to $z = 0.016054$ (Willmer et al. 1991), except for that of the *XMM-Newton* and *NuSTAR* $x_{\text{il-}}\text{verCp}$ components, which we tie together but leave free in order to circumvent some apparent calibration issues (presumably with the gain scale). The resulting small shift to the narrow iron line from the known redshift of $\Delta z \approx 7 \times 10^{-3}$ enormously improves the fit ($\Delta\chi^2 = 34$, 5.7σ improvement according to an F-test), likely indicating a small error in the *XMM-Newton* and *NuSTAR* gain scales. High-resolution *Chandra* spectroscopy of IC 4329A has previously confirmed that the most prominent narrow iron line is at ≈ 6.3 keV (McKernan & Yaqoob 2004), which is as expected for neutral iron emission (6.4 keV in the rest frame) redshifted by the known redshift of the host galaxy. In our fits, the narrow line is instead at ≈ 6.26 keV. Moreover, when the *XMM-Newton* and *NuSTAR* models are allowed to have different redshifts to one another, χ^2 once again improves significantly, with the redshift being greater for *NuSTAR* and both being significantly discrepant with the host galaxy value. No other parameters are affected though. A very similar issue is seen in *XMM-Newton* and *NuSTAR* data taken as part of *IXPE* campaigns on two other Seyfert 1 galaxies: MCG-05-23-16 (Marinucci et al. 2022; Tagliacozzo et al. 2023) and NGC 4151 (Gianolli et al. 2023).

Table 1 lists the best-fitting parameters of the cross-calibration model mbpo. We arbitrarily take *NuSTAR* FPMA as the ‘ground truth’ and find that we only need to multiply the FPMB model by a constant to achieve acceptable agreement with the FPMA. We multiply the *XMM-Newton* model by a single power law ($\Delta\Gamma_2 = \Delta\Gamma_1$) and find that the index $\Delta\Gamma_1$ is small and consistent with zero within 1σ confidence. For *IXPE*, we find that only a single corrective power law is required for DU1, whereas broken power laws are required for DU2 and DU3 (as is also found for Cygnus X-1; Krawczynski et al. 2022). This indicates that the effective area of DU2 and DU3 drops off above $E \sim 7$ keV more steeply than the current calibration files suggest (and this is currently being investigated by the calibration team), although the slope (i.e. $\Delta\Gamma_2$) is poorly constrained by our fits due to the lack of photons with these energies. The lack of $E > 7$ keV photons also means that this calibration issue has no influence on the measured polarization.

3.3 Spectropolarimetric fit

We now include *IXPE* Stokes Q and U into our spectral fit. We first extend Model 1 by assigning a constant (i.e. independent of energy) PD and PA to each component with the `polconst` convolution model. This is a very crude approximation for the reflection component, which includes an essentially unpolarized iron line and a potentially highly polarized reflection continuum. Because the iron line is the most prominent contributor to reflection in the *IXPE* band, we first freeze the PD of both reflection components to zero and leave the `nthcomp` PD and PA as free parameters. This effectively equates to assuming that the direct coronal emission dominates the 2–8 keV polarization, which is justifiable as this component contributes the most flux in the band (66 percent). Fitting this model to the spectral-polarimetric data gives $\chi^2/\text{d.o.f.} = 1267/1219$. The best-fitting model spectrum and unfolded data for

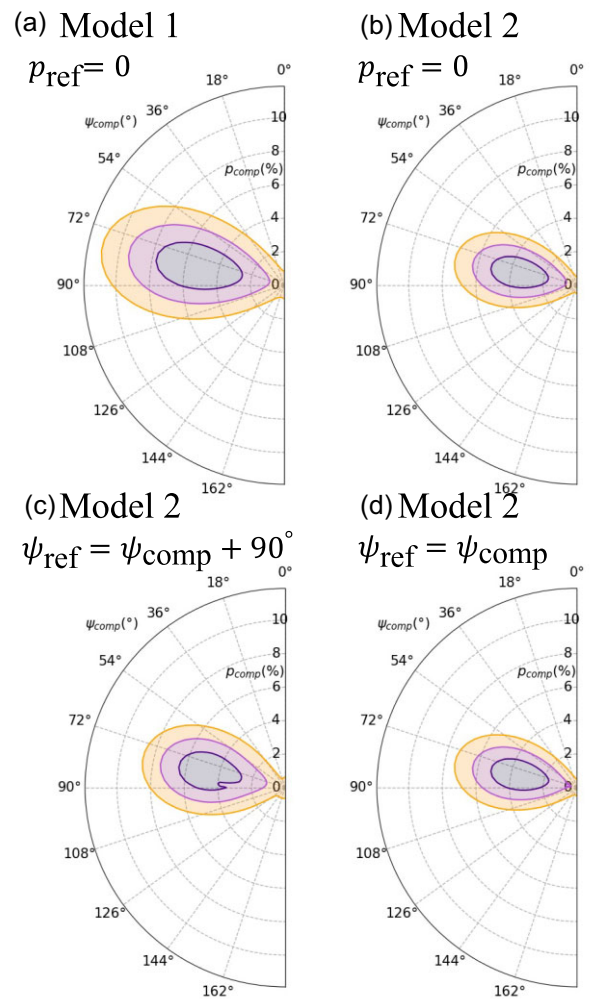

Figure 7. Constraints on the coronal PD (p_{comp}) and PA (ψ_{comp}) for different modelling assumptions. Three contours correspond to the 68, 90, and 99 per cent confidence levels. (a) Results for Model 1 assuming zero PD of the reflection component $p_{\text{ref}} = 0$. (b) Results for Model 2, also assuming $p_{\text{ref}} = 0$. (c) Results for Model 2 with $\psi_{\text{ref}} = \psi_{\text{comp}} + 90^\circ$ and p_{ref} free to vary. (d) Results for Model 2 with $\psi_{\text{ref}} = \psi_{\text{comp}}$ and p_{ref} free to vary. p_{ref} is unconstrained whenever it is left free to vary in the fit.

Stokes Q and U are shown in Fig. 4(c). All spectral parameters are almost completely unchanged from the values quoted in Table 1.

The resulting coronal PD and PA values are quoted in Table 2 (top row), and their confidence contours are plotted in Fig. 7(a). We see that the coronal PA here is consistent with the overall 2–8 keV PA presented in Fig. 3, whereas the PD is larger, as are the uncertainties. This is because we have assumed the reflection components, which contribute ~ 34 per cent of the 2–8 keV flux, to be unpolarized. The resulting dilution increases the best-fitting coronal PD by a factor of $\sim 1/0.66$.

To explore a more realistic scenario with an unpolarized iron line and a polarized reflection continuum, we define a new spectral model that we dub Model 2:

$$\text{mbpo} \times \text{ztbabs} \times \text{tbabs} \\ \times [\text{cutoffpl} + \text{pexriv} + \text{laor} + \text{gauss}]. \quad (3)$$

The direct coronal emission is now represented by an exponentially cut-off power law, `pexriv` (Magdziarz & Zdziarski 1995)

represents polarized reflection (i.e. unlike `xillverCp`, the `pexriv` spectrum does not include an iron line), `laor` (Laor 1991) is a relativistic iron line and the narrow (width fixed to 0.05 keV) Gaussian is the iron line from the distant reflector. This model is less sophisticated as a spectral model, but enables us to treat the polarization of the lines separately to other aspects of the reflection signals. When we fit this model to the joint *XMM-Newton*, *NuSTAR*, and *IXPE* Stokes *I* data, we achieve a fit of similar quality with $\chi^2/\text{d.o.f.} = 1110/1047$. The best-fitting Model 2 parameters are quoted in Table 3, and the best-fitting model is plotted in Fig. 6. Fitting Model 2 without the `laor` component yields $\chi^2/\text{d.o.f.} = 1125/1050$, meaning that the relativistically broadened iron line is required with 3.1σ confidence (according to an *F*-test). Moreover, the best-fitting r_{in} and i values agree between Models 1 and 2.

Although the iron line is consistent between Models 1 and 2, the reflection continuum is quite different, with the direct continuum contributing 97 per cent of the 2–8 keV flux for Model 2 as opposed to 66 per cent for Model 1. This is because Model 2 makes the crude approximation that the reflection continua of the two reflection components can simply be summed together and represented by one `pexriv` component. In reality, we expect the relativistic reflector to be highly ionized and the distant reflector to be approximately neutral. This behaviour is captured by Model 1, with the `relxillCp` spectrum being much softer than the `xillverCp` spectrum due to its higher ionization parameter. Model 2 is not as flexible: the fit can either choose a low ionization to reproduce the distant reflection continuum or a high ionization to reproduce the relativistic reflection continuum. The best-fitting ionisation parameter is low ($\xi \approx 80 \text{ erg cm s}^{-1}$), and thus the `pexriv` contribution is very small in the soft X-rays. We tried including an extra neutral reflection continuum in Model 2 (`pexrav`), but this model proved highly degenerate.

We then include the Stokes *Q* and *U* spectra into our Model 2 fit, again by convolving each additive spectral component with `polconst`. We freeze the polarization of the two line components (`laor` and `gauss`) to zero and try several assumptions for the PD and PA of the direct and reflected components: p_{comp} , ψ_{comp} , p_{ref} , and ψ_{ref} . The resulting confidence contours for p_{comp} and ψ_{comp} are plotted in Fig. 7(b)–(d), and their values are quoted in Table 2. Panel b shows the results assuming $p_{\text{ref}} = 0$. We see that the PA is consistent with the Model 1 result (panel a), but the PD is now smaller. This is because of the much smaller 2–8 keV contribution from reflection in the Model 2 fit (3 per cent as opposed to 34 per cent). The dilution from the unpolarized component is therefore smaller and the coronal PD comes out at a similar value to the overall 2–8 keV PD. Panel c shows the results assuming direct and reflected components are polarized perpendicular to one another, as would be expected if, for example, the corona is vertically extended (see Fig. 1). In this case, the total polarized flux is the difference between that of the two spectral components. The coronal PD is therefore larger than in panel b to offset this subtraction. The PD of the reflection component is completely unconstrained (all values from 0 to 100 per cent are acceptable within 1σ confidence), and the small difference between panels b and c illustrates that its best-fitting value is small. Panel d presents the results assuming the two components have parallel polarization (as would occur if, for example, the corona is radially extended; see Fig. 1), meaning that the polarized flux is summed over the two components. The coronal PD is therefore slightly smaller than in panel b, due to a small (albeit still completely unconstrained) contribution from the reflection component.

Figure 8. ALMA image of IC 4329A at 100 GHz. The colour scheme runs from twice the noise level up to the peak value of the core, with square-root scaling. Contours are 4, 10, 20, 80, and 100 times the noise level. The Gaussian restoring beam (plotted bottom-left) is $0.07 \text{ arcsec} \times 0.065 \text{ arcsec}$ with a major axis position angle of 85° . The black dotted lines demonstrate position angles of 78° and 90° (measured east of north).

4 DISCUSSION

4.1 Multiwavelength comparison

Although not significant above the 3σ level, we find that the 1σ confidence range on the 2–8 keV PA of IC 4329A is $\psi = 78^\circ \pm 10^\circ$. Our spectropolarimetric analysis yields similar constraints on the PA of the corona. Optical and infrared polarization (Wolstencroft et al. 1995) instead align with the $\approx 45^\circ$ position angle of the galaxy disc (see e.g. fig. 1 of Bentz et al. 2023), indicating that it is consistent with dust scattering in the galactic dust lane. Radio emission can be seen to extend along the position angle $\sim 90^\circ$ in the highest resolution 1.5 and 5 GHz Very Large Array (VLA) images in the literature (Unger et al. 1987, beam diameters ~ 3 and $\sim 1.5 \text{ arcsec}$, respectively). These images resemble a marginally resolved jet, with extended emission appearing only to the west of the core.

In Fig. 8, we present a high resolution (beam diameter $\sim 0.07 \text{ arcsec}$, corresponding to $\sim 10 \text{ pc}$) 100 GHz image of IC 4329A made from a September 2021 observation by the Atacama Large Millimeter/sub-millimeter Array (ALMA).³ We see that the extended emission is consistent with the $\sim 90^\circ$ position angle inferred from longer wavelength images, but also with our measured $\sim 78^\circ$ X-ray PA (black dotted lines). We again see extended emission on only one side, but unlike at 1.5 and 5 GHz, the extension is to the East of

³c 2019.1.00580.S (PI: Y. Inoue) with a total integration time of 254 s. We used public pipeline-processed data products from the ALMA archive, reduced using CASA version 6.2.1.7. Three spectral windows were combined, and the imaging was done using the CASA task `TCLEAN`, adopting a Briggs weighting scheme with a robustness parameter of 0.5. The 12-m array configuration used for the observations allow a maximum recoverable scale of 1.2 arcsec, so the images are not sensitive to any emitting structures larger than this.

the core, not the West. It therefore seems unlikely that the jet is one sided due to Doppler boosting of the approaching jet and Doppler suppression of the receding jet, in which case the extension would be on the same side for all different scales imaged. It is instead more likely that the jet bulk Lorentz factor is low enough for Doppler boosting to be unimportant, and the intrinsic brightness of the jet is not uniform, perhaps with regions of enhanced radio emission corresponding to overdensities that the jet is passing through.

We conclude that the X-ray polarization is broadly consistent with the jet direction, as is observed more conclusively for the black hole X-ray binary Cygnus X-1 (Krawczynski et al. 2022), the neutron star X-ray binary Cygnus X-2 (Farinelli et al. 2023) and the AGN NGC 4151 (Gianolli et al. 2023). Fig. 8 provides a tentative hint that the small scale jet imaged at 100 GHz aligns with the X-ray PA, with the jet perhaps bending around to $\sim 90^\circ$ on the larger scales probed by the VLA images. Even if we take 90° as the most likely jet position angle, we find that forcing the X-ray polarisation to be parallel or perpendicular to it gives 99 per cent confidence ranges on the PD of, respectively, 3.0 ± 2.9 per cent and < 1.2 per cent. A radially extended corona (which would be polarized parallel to the jet) is therefore much more compatible with our results than a vertically extended corona (which would be polarized perpendicular to the jet); see Fig. 1.

4.2 Spectral fits

We fit two models to the *IXPE*, *XMM-Newton*, and *NuSTAR* spectra. In Model 1, the relativistic and distant reflection components are modelled, respectively, with `relxillCp` and `xillverCp`. Model 2 instead uses `laor` for the relativistic iron line, a Gaussian for the narrow line, and `pexriv` for the remainder of the reflection spectrum. Both models prefer a small disc inner radius ($r_{\text{in}} \approx 2 r_g$) and low inclination (at 90 per cent confidence, $i < 26^\circ$ for Model 1 and $i < 45^\circ$ for Model 2), albeit with rather large statistical uncertainties (Fig. 5), and potentially larger systematic uncertainties. The relativistic component is statistically required for both models. The `relxillCp` component is required in Model 1 with 5.1σ significance. However, it is not possible to disentangle whether it is the broad iron line itself that is required in the Model 1 fit, or whether it is instead the contribution of `relxillCp` to the broad-band continuum. It is therefore encouraging that the `laor` component is also required in the Model 2 fit (3.1σ confidence), providing an indication that a broad line is indeed present in the data. It is also somewhat encouraging that Models 1 and 2 return consistent estimates of r_{in} and i .

The ionization parameter of the relativistic reflector and the iron abundance of both reflectors are uncomfortably high in the Model 1 fit. Exploration of parameter space reveals that this combination of parameters is driven by the Compton hump being relatively weak, given the strength of the narrow iron line and the relatively hard illuminating spectrum. When we untie the iron abundance of the two reflectors, A_{Fe} of the distant reflector increases further. When we instead replace the distant reflector with a narrow Gaussian iron line, such that only the relativistic reflector contributes a Compton hump, the high $\log \xi$ and A_{Fe} values persist for the relativistic reflector. The high iron abundance therefore appears to be driven by both the relativistic and distant reflectors. We find that an acceptable fit ($\chi^2/\text{d.o.f.} = 1107/1048$) can be achieved by fixing abundance and ionization to reasonable values ($A_{\text{Fe}} = 1$ and $\log \xi = 3.6$) when we untie the photon index of the illuminating spectrum from the observed value. In this fit, the disc sees a softer coronal spectrum ($\Gamma \approx 2.2$) than we see ($\Gamma \approx 1.7$), which is physically plausible because

we are viewing from a low inclination angle whereas the disc is viewing from $i \sim 90^\circ$. The softer illuminating spectrum enables the iron lines to be stronger with respect to the Compton humps without the need for strongly super-solar iron abundance.

A highly super-solar iron abundance is a common feature of reflection fits in the literature (García et al. 2018), and has previously been shown to be at least partially remedied by considering higher disc densities (Tomsick et al. 2018), at least in the case of X-ray binaries. However, here we ignore the $E < 2$ keV energy range that is most sensitive to the density (although we note that reflection models still have some sensitivity to density for $E > 3$ keV; Ingram et al. 2022; Liu et al. 2023) and thus choose to fix it to the canonical value for AGNs of $n_e = 10^{15} \text{ cm}^{-3}$. Moreover, here we assume a single ionization parameter throughout the disc, whereas in reality we expect the ionization parameter to be a function of radius (Svoboda et al. 2012; Ingram et al. 2019). Finally, Kinch et al. (2019) found (albeit for parameters relevant to X-ray binaries), that a very strong iron line can result from self-consistent radiation treatment of general relativistic magnetohydrodynamic simulations, even when solar abundances are assumed.

Whereas consistent disc inclination and inner radius values are returned for all the models we explore, we find that different models return different values of the coronal electron temperature. For Model 1, it is $kT_e \approx 40$ keV, whereas for Model 2, it can be estimated from the exponential cut-off as $kT_e \approx E_{\text{cut}}/2 \approx 200$ keV. The discrepancy likely comes from the dependence of the shape of the reflection spectrum on kT_e (García et al. 2015). We must therefore consider a range of electron temperature values when comparing the observed polarisation to coronal models.

4.3 Coronal geometry

The measured PA being roughly aligned with the radio jet favours models in which the corona is radially extended in the plane of the disc, assuming that any misalignment between the jet and the disc rotation axis is small. We can in principle differentiate between different radially extended geometries using the PD (Schnittman & Krolik 2010; Ursini et al. 2022), which we measure to be $p = 3.3 \pm 1.1$ per cent (1σ confidence) in the 2–8 keV band. In Fig. 9, we plot the predicted PD of various coronal geometries as a function of the cosine of inclination angle. The hatched areas represent the 90 per cent (cyan) and 3σ (grey) confidence regions of the 2–8 keV PD measured by *IXPE*, and the inclination angle returned from our Model 1 spectral fit. Our low best-fitting inclination (the 90 per cent statistical upper limit is $i < 26^\circ$, although there are surely also systematic uncertainties, which are hard to quantify) agrees with previous estimates of the inclination to the inner disc and broad-line region (Marin 2014; Bentz et al. 2023), and with the Seyfert 1.2 classification of the source in the context of the AGN unification scheme (Urry & Padovani 1995). Whereas the PD is consistent with zero within 3σ confidence, at 90 per cent confidence the measured PD is > 1.44 per cent.

The left-hand panel considers a slab corona located above the disc and extending radially from $6r_g$ to $100r_g$ (black hole spin assumed to be $a = 0$). Here, the polarization in the source frame is calculated using an iterative radiation transport solver (COMPSS; Poutanen & Svensson 1996; Veledina & Poutanen 2022), and then relativistic effects are accounted for using an analytic approximation of the Schwarzschild metric (Poutanen 2020). Circular markers represent a static corona, and triangles a vertically out-flowing corona (Poutanen, Veledina & Beloborodov 2023). Because there is some uncertainty in our spectral fits, we trial three values of the

Figure 9. PD of various coronal geometries as a function of the cosine of the inclination angle. For all geometries considered, the PA is perpendicular to the disc plane. The hatched areas represent the observed PD and inclination at 90 per cent (cyan) and 3σ (grey) confidence. *Left:* A slab corona extending from $6r_g$ to $100r_g$, calculated using iterative radiative transfer solver COMPPS for three values of electron temperature. Static (circles) and out-flowing (triangles) configurations are considered. *Right:* Slab and wedge coronal geometries, calculated using the Monte Carlo code MONK, assuming a static corona with an electron temperature of $kT_e = 40$ keV. The slab extends to the ISCO, and two values of black hole spin are considered: $a = 0$ (black circles, same case as solid black line in the left-hand panel) and $a = 0.998$ (red squares). The wedge has opening angle of 45° and outer radius $25r_g$, and two assumptions are made about the disc: extending to the ISCO (magenta stars), and truncated at $25r_g$ (blue triangles).

electron temperature: $kT_e = 40$ keV (as inferred from our Model 1 fit; solid black line), $kT_e = 100$ keV (dashed lines), and $kT_e = 200$ keV (as inferred from our Model 2 fit; dotted blue line). For each electron temperature, we choose a coronal optical depth that returns the measured photon index of $\Gamma = 1.66$ (corresponding to the Thomson optical depth of the slab $\tau = 2.3, 0.95,$ and $0.43,$ respectively).

We see that PD typically increases with inclination angle, which occurs because the projection of the corona on the sky becomes increasingly asymmetric for larger inclinations. We also see that the highest values of PD are achieved for the intermediate value of electron temperature. This occurs because of a trade-off between two different effects. First, for a given Γ , higher temperature corresponds to lower τ (e.g. Middei et al. 2019). The lower the optical depth, the less likely it is that photons can have multiple scatterings in the vertical direction (i.e. perpendicular to the disc plane), and thus the more likely it is that any photons that did have multiple scatterings were travelling horizontally before they scattered. Because photons are most likely to be scattered in the plane perpendicular to their polarization vector, lower τ leads to stronger vertical polarization (see Fig. 1). The second, competing, effect occurs because higher electron temperature leads to higher electron velocities. This leads to scattered photons being more heavily beamed into the random direction of motion of the electrons, diluting the correlation between the post-scattering trajectory and polarization of photons (Poutanen 1994).

The right-hand panel of Fig. 9 presents results from the relativistic Monte Carlo radiative transfer code MONK (Zhang, Dovčiak & Bursa 2019), assuming a static corona with temperature $kT_e = 40$ keV. The black line with circular markers corresponds to the same geometry as before: a slab extending from $6r_g$ to $100r_g$ ($a = 0$). We see very good agreement with the COMPPS calculation (black solid

line in the left-hand plot) at the low inclination angles of interest, with some discrepancies at high inclinations that will be explored in future work. We also plot results for a slab extending to the ISCO of a maximally spinning black hole (red squares). We see that relativistic effects significantly affect the polarization for $i \gtrsim 60^\circ$, but not at the lower angles relevant to IC 4329A. We finally consider a uniform density wedge corona with opening angle 45° extending from the ISCO of a maximally spinning black hole to $25r_g$ (Tagliacozzo et al. in preparation). In one case, the disc extends within the corona down to the ISCO (magenta stars), and in the other case it is truncated at the outer radius of the corona (blue triangles). These two geometries return a lower PD than the slab because they are less asymmetric.

It is interesting that, in the 90 per cent confidence limit, the observed PD (cyan hatched markings) lies above the predictions of all static corona models for the inferred inclination angle. Assuming instead that the coronal electrons are out-flowing with a mildly relativistic bulk velocity away from the disc plane ($0.4c$ in Fig. 9, left) boosts the predicted polarization into the observed range (due to relativistic aberration). Such an out-flowing model was recently proposed by Poutanen et al. (2023) to explain the high observed PD from Cygnus X-1, and is also consistent with our results. We further note that including an out-flowing bulk velocity solves a key problem of the slab model, in that a static slab should not be able to self-consistently produce the hard ($\Gamma < 2$) spectrum that is observed because it is irradiated by too high a flux of soft disc photons (Haardt & Maraschi 1993; Stern et al. 1995; Poutanen et al. 2018). A bulk velocity solves this problem because it reduces the incident seed photon flux via Doppler de-boosting (Beloborodov 1999). Including a bulk velocity will also enable the wedge and truncated disc geometries to reproduce our polarization results.

5 CONCLUSIONS

We have conducted a spectro-polarimetric analysis of IC 4329A using *IXPE*, *XMM-Newton*, and *NuSTAR*. Our *IXPE* measurement of 2–8 keV polarization falls just short of the 3σ detection threshold (significance 2.97σ). The 1σ confidence limits on PD and PA are $p = 3.3 \pm 1.1$ per cent and $\psi = 78^\circ \pm 10^\circ$, respectively. The PA is roughly consistent with the radio jet position angle, once uncertainty on the jet orientation is taken into account. We jointly model the *XMM-Newton*, *NuSTAR*, and *IXPE* spectrum, confirming the presence of a relativistic reflector. Reflection modelling prefers a low inclination ($<26^\circ$ with 90 per cent confidence), which is consistent with previous measurements of the viewing angle of the broad line region and the object's Seyfert 1.2 classification within the AGN unification scheme. This constraint coupled with our 90 per cent confidence lower limit on PD of 1.4 per cent tentatively favours more asymmetric, possibly out-flowing, coronal geometries extended in the disc plane that would produce highly polarized emission aligned with the jet, but the coronal geometry is unconstrained at the 3σ level. Reflection modelling also favours a small disc inner radius, but does not constrain black hole spin because disc truncation outside of the ISCO is statistically acceptable within the 3σ limit. Spectro-polarimetric modelling is consistent with the 2–8 keV polarization being dominated by emission observed directly from the corona, but the contribution from reflection is unconstrained.

ACKNOWLEDGEMENTS

The *IXPE* is a joint US and Italian mission. The US contribution is supported by the National Aeronautics and Space Administration (NASA) and led and managed by its Marshall Space Flight Center (MSFC), with industry partner Ball Aerospace (contract NNM15AA18C). The Italian contribution is supported by the Italian Space Agency (Agenzia Spaziale Italiana, ASI) through contract ASI-OHBI-2017-12-I.0, agreements ASI-INAF-2017-12-H0 and ASI-INFN-2017.13-H0, and its Space Science Data Center (SSDC) with agreements ASI-INAF-2022-14-HH.0 and ASI-INFN 2021-43-HH.0, and by the Istituto Nazionale di Astrofisica (INAF) and the Istituto Nazionale di Fisica Nucleare (INFN) in Italy. This research used data products provided by the *IXPE* Team (MSFC, SSDC, INAF, and INFN) and distributed with additional software tools by the High-Energy Astrophysics Science Archive Research Center (HEASARC), at NASA Goddard Space Flight Center (GSFC). We thank the *XMM-Newton* and *NuSTAR* SOCs for granting and performing the respective observations of the source. Part of the French contribution is supported by the Scientific Research National Center (CNRS) and the French Space Agency (CNES). AI and ME acknowledge support from the Royal Society. We thank the anonymous referee for insightful comments that improved the clarity of the paper.

DATA AVAILABILITY

The *IXPE* data used in this paper are publicly available in the HEASARC data base (<https://heasarc.gsfc.nasa.gov/docs/ixpe/archive/>). The *XMM-Newton* and *NuSTAR* data underlying this article are subject to an embargo of 12 months from the date of the observations. Once the embargo expires the data will be publicly available from the *XMM-Newton* science archive (<http://nxs.a.esac.esa.int/>) and the *NuSTAR* archive (https://heasarc.gsfc.nasa.gov/docs/nustar/nustar_archive.html). The simulation data supporting the findings of the article will be shared on reasonable request.
