(Received 16 September 1993; accepted 20 April 1994)

Following our recent report on the successful fabrication of "stationary" MTG Bi$_{1.6}$Pb$_{0.4}$Sr$_2$Ca$_2$Cu$_3$O$_y$ pellets in a simple tube furnace, we have tried many heating programs with various "crystal growth starting temperatures", $T_s$, and sintering temperatures, $T_s'$; the samples are sintered for 20–40 h before quenching in air. It is found that $T_s-T_s'$ should be rather narrow to produce good MTG samples, and the typical value of $J_c$ is enhanced from $100$ A cm$^{-2}$ (for a polycrystalline sample) to about $3 \times 10^3$ A cm$^{-2}$ for our good ones. SEM and TEM results indicate that the samples are full of packs which contain highly oriented mica-like layers.

INTRODUCTION

There are several crucial aspects to make fabrication of the Bi-class MTG samples a success. The first technical problem one faces is the loss of sample material when the sample is heated to melt. We have to find a substrate that reacts with the melt liquids to form crystals, basically of the Bi-class members at a slow rate. The "unwanted layer" can be ground off after sintering, leaving a substantial amount of desired superconducting material. We have found in our previous investigation that the pellet made of Sr with the same $T_s$ as the sample will serve the stated purpose. The second problem one faces is to find the right temperature for crystal growth to commence. Of course, the cooling temperature has to be within a (narrow) range to sustain the growth of single crystal-like layers or lumps. It is also anticipated that nuclei should exist inside the sample to help the growth process. While Y$_2$BaCuO$_5$ is guessed to be the nuclei for the Y-123 specimens, the CaO particles are conjectured to be possibly the nuclei in the Bi-class samples, and the solid-state reaction method consists of two steps as described in Ref. 1.

The MTG heating program for stationary sample(s) placed near the ends of a simple tube furnace can be

considered to be made of six heating stages. In stage (i), the tube is heated to the maximum temperature $T_m$ of the heating program with a rate that is not at all critical (Fig. 1). It is believed that some particles must act as nuclei for crystal growth, and one natural theory is to make $T_m$ higher than the melting temperatures of all compounds except perhaps one. Since the melting temperature of CaO powder is 2614 °C, $T_m$ is chosen to be 950 °C at which compounds of Bi, Sr, and Cu have already melted and CaO is the “added ingredient” after preheating the precursor BiSrCuO. The sample is left in the melt state for a brief period of a few tens of minutes. It is then suddenly cooled, again with a rate that is not critical, to a crucial temperature $T_c$, which may be called the “crystal growth starting temperature”.

A slow cooling begins with a crucial rate of say $D$ °C/h, until the temperature is $T_e$, the sintering temperature. The sample is sintered for tens of hours at $T_e$ and is either quenched (in air, liquid nitrogen) or cooled in a furnace. In Ref. 1, we have found out that a workable program is specified by $T_m = 950$ °C, $T_c = 890$ °C, $T_e = 870$ °C, and $D = 0.5$ °C/h. We have tried many programs since then, and we report in this paper the results of some typical ones, leading to the establishment of an optimum heating program for samples with the prescribed stoichiometric ratio.

II. FABRICATION AND CHARACTERIZATIONS

First, we preheated the mixture of Bi$_2$O$_3$, PbO, SrO, and CuO according to the stoichiometric ratio Bi$_{1.6}$Pb$_{0.4}$Sr$_2$Ca$_2$Cu$_3$O$_y$ at a temperature of 750 °C for 40 h. The partially crystallized material was then ground with CaO powder in a 1 mm$^2$ wafer and shaped in a pellet of 1 cm diameter. The two pellets were placed in a crucible, then a location with a heating power of 950 °C, and kept at 950 °C for parameterization.

We selected a few samples from among the four, and the last one to be the sample with $D = 0.5$ °C/h. We tested the samples specified as A, B, C, D, and E.

The samples were then subjected to three fabrication processes: heating, quenching, and four-probe measurement. The $R$-$T$ curves are shown in Fig. 2, and the SEM micrographs of the samples are shown in Fig. 3.

with CaO powder based on the nominal composition Bi$_{1.6}$Pb$_{0.4}$Sr$_2$Ca$_2$Cu$_3$O$_y$, and a pellet of size 11 × 5 × 4 mm$^3$ was made under a pressure of 8 tons. Another pellet of the same size was made of SrO powder and the two pellets were stacked and placed on a common movable; the middle of the sample was adjusted to be at the location where the temperature gradient was 10 °C/cm at 950 °C. We specified the heating program by the four parameters $T_m$, $T_i$, $T_r$, and $D$ described in the last section. We shall not list all the trials, but will introduce among these five special programs one that was found to be the optimum. In these programs, $D$ was fixed to be 35 °C/h, $T_m$ to be 950 °C, and $T_i$ and $T_r$ satisfy numbers specified in Table I. The heating programs A, B, C, D, and E correspond to the specimens fabricated A, B, C, D, and E, respectively.

The other parameters are depicted in Fig. I. After fabrication, the five samples were tested with the usual four-probe techniques, and Fig. 2 depicts these five $\rho$-$T$ curves. The usual $\chi$-$T$ curves were measured with a commercial APD SSC characterization set (see Fig. 3). SEM morphology using our Cambridge Stereoscan S150 microscope operated with a magnification of 2000× revealed that the crystals did grow to form stacks of layers, though spaces were found between such stacks [Figs. 4(a)–4(e)]. As the mass density of these samples is only about 3.1–3.9 g cm$^{-3}$ (cf. over 5.4 g cm$^{-3}$ for the good Y-123 MTG samples), we should expect that there must be empty space around the interior of each sample. Mechanical pressing has been used to fabricate the Bi-class of SSC wires by others, and we must improve the mass density of the MTG Bi-class samples at a slightly later stage. It suffices to develop a suitable MTG process for the Bi-class samples now. Increasing the SEM magnification to 5000×, we observed mica-like structure of the crystals in the micron scale [Figs. 5(a)–5(e)]. Thus, within one stack of “crystal sheets”, the layers in the 1 μm–10 μm scale are tightly packed indeed.

A small portion of sample C was ground, and films of thickness ~70–80 nm were prepared in the manner stated in Ref. 12 for TEM (Model: JEM JEOL 2000FX) observation. Figure 6(a) is a typical TEM micrograph that shows massive dislocation in the grain. Since the

c-axis of a Bi-sample (either the 2212 or 2223 phase) is relatively large, the dislocation energy is smaller in a MTG sample as compared to that of a solid-state reaction sintered sample. Moreover, in Fig. 6(b), we can observe parallel lattice fringes which are believed to represent the (001) planes of the orthorhombic crystals. The av-

III. ANALYSIS AND CONCLUSIONS

(1) We have reported five heat programs that will produce successful MTG Bi-samples, satisfying the stated stoichiometric ratio. The melting point of the precursor Bi$_{1.6}$Pb$_{0.4}$Sr$_2$Ca$_2$Cu$_3$O$_y$ is lower than 870 °C so that we can operate $T_s$ at or slightly above 870 °C. From R-T and $\chi$-T results, it appears that program B is the optimum one; i.e., it is suitable to choose $T_s = 880$ °C, $T_c$ has to be the temperature at which the 2223 phase is formed, which is 860 °C. If we choose a lower $T_c$ value, surely more 2212 phase crystal will be formed. Thus, the ranges of $T_s$ and $T_c$ are rather restrictive, and the best one so far found for the specimen (Bi$_{1.6}$Pb$_{0.4}$) is simply program B: $T_s = 880$ °C, and $T_c = 860$ °C.

(2) Though we have not fabricated MTG samples with pure 2223 phase, we believe it is not difficult to make such samples if we proceed with a similar systematic analysis of the thermal treatment and the characteristics of the consequential samples. In particular, the sintering time is only 40 h at $T_s$. It is well established that by elongating the sintering time to about seven days, closely to pure 2223 phase can be obtained. In fact, several years of research on polycrystalline Bi-samples indicates that main object of the Bi-samples are $T_m$, $T_c$, $T_{c'0}$, etc., can be deduced by R-T and $\chi$-T.

(3) The success of this work as a successor to previous work is characterized by the clarity of temperature range, the production of temperature control, and a major improvement in the features and the micromorphism. Good ones in terms of the microstructure are not so far published due to the crystal layer creep, random orientation and samples size are very small scale. V-shaped alignment of MTG Bi-samples developed in our laboratory has macroscopically measured $T_m$, $T_c$, and $T_{c'0}$, and $T_{c'p}$ are very high and can be measured to about 400 °C, much higher than those reported in the presented results.

IV. SUMMARY

We have demonstrated that a new program for the fabrication of superconducting MTG Bi-samples in different conditions. The temperatures $T_m$, $T_c$, and $T_{c'p}$ can be varied with the temperature $T_s$. Our results show that the $T_m$, $T_c$, and $T_{c'p}$ in our hours' samples are much higher than the typical ones reported by other authors and $T_c$ was measured as high as 860 °C. The samples are substantially pure MTG Bi-samples, with a grain size in the range of 1-5 microns. The results presented here show that the MTG Bi-samples can be made using a single-stage high-temperature sintering process, which is economical and efficient.
several years ago we fabricated 95% pure 2223 phase polycrystalline samples with Pb and V doping.\textsuperscript{16,17} The main objective here is to report the workable values of $T_1$, $T_2$, $T_e$, and $D$ from which an optimum program is deduced by experiment.

(3) That the heating program can be considered as a successful one is based on the revelation of MTG characteristics. We have learned from experiment that crystals grow along the direction of negative gradient of temperature.\textsuperscript{5} Single crystal-like layers are formed, and a majority of the weak links are eliminated. Such features are shown directly and indirectly in the SEM micrographs. Figures 5(a)–5(c) can be considered very good ones according to the SEM of Bi-class samples so far published. We must note that the highly oriented crystal layers form stacks that may show somewhat random orientation directions while good MTG YBCO samples show layered structure stretching over the mm scale.\textsuperscript{2,4} We have not achieved such large scale crystal alignment for the Bi-class yet. However, our technology developed so far will definitely help us to make MTG Bi-samples with better texture and microstructure; the microscopic features are related in our analysis. With measured $J_c$, SEM, TEM morphology, etc., we can confidently fabricate MTG Bi-samples with a mass density much higher than 3.9 g cm$^{-3}$ and $J_c$ much greater than the present values of several times 10$^3$ A cm$^{-2}$.

W. SUMMARY

We have successfully found an optimum heating program for fabricating MTG Bi$_{1.6}$Pb$_{0.4}$Sr$_2$Ca$_2$Cu$_3$O$_y$ superconductors in a simple tube furnace. In this paper, different parameters including crystal growth starting temperature ($T_s$) and sintering temperature ($T_s$) were varied with the cooling rate (D) and maximum temperature ($T_m$) fixed to 0.5 °C/h and 950 °C, respectively, in our heating program. Through a lot of trials, five typical programs, namely A, B, C, D, and E, with $T_s$ and $T_e$ values corresponding to Table I were reported here. According to the $R$-$T$ and $x$-$T$ relationships, as well as the SEM and TEM morphology of the above five specimens, it appears that program B with $T_s = 880$ °C and $T_e = 860$ °C is the optimum one. Using this program, we can make MTG BSCO specimens with better texture as well as good microstructure and macroscopic characteristics compared with that of polycrystalline BSCO specimens.
