(Received 12 December 2000; published 13 March 2001)

We present an ab initio analysis of electron conduction through a C₆₀ molecular device. Charge transfer from the device electrodes to the molecular region is found to play a crucial role in aligning the lowest unoccupied molecular orbital of the C₆₀ to the Fermi level of the electrodes. This alignment induces a substantial device conductance of \( \sim 2.2 \times (2e^2/h) \). A gate potential can inhibit charge transfer, and introduce a conductance gap near \( E_F \), changing the current-voltage characteristics from metallic to semiconducting, thereby producing a field-effect molecular current switch.

Understanding electron conduction in atomic and molecular scale nanodevices is an extremely active research topic at present.¹⁻⁶ The current voltage (I-V) characteristics of many molecular devices have shown profound potentials for device application, including high nonlinearity, negative differential resistance, and electromechanic current switching. However, a thorough understanding of electron transport mechanisms at this scale, which will play a crucial role in designing operation principles for future nanoelectronics, has not yet been achieved. To provide insight into electron conduction mechanisms at atomic and molecular scales, we have investigated the quantum transport properties of a C₆₀-based molecular device using a first-principles theoretical method.

Experimentally, the C₆₀ molecular electromechanical amplifier⁷ demonstrated that electric current flowing through a C₆₀ molecule could be amplified by as much as 100 times when the molecule was mechanically deformed. This phenomenon was attributed to an increase of the tunneling density of states at the Fermi level induced by mechanical deformation.¹,⁷ While this conduction mechanism is very interesting, a natural question is whether or not there are other, perhaps simpler, physical mechanisms which can be exploited for molecular scale electron conduction? Our analysis suggests an interesting mechanism based on charge transfer doping: because of its high electronegativity, a well-contacted C₆₀ gains charge from charge transfer, thereby aligning its lowest unoccupied molecular-orbital state to the Fermi level of the electrodes, resulting in a substantial device conductance without the need of mechanical deformation. Charge transfer was seen to have reduced the conductance of a short carbon chain,⁸ but, for the more complex C₆₀ molecule, it does the opposite by drastically increasing conduction. Current switching mechanisms are another important yet unsettled question of nanoelectronics. Our analysis further suggests an interesting principle for molecular switching by controlling the charge-transfer doping with a gate voltage.

The C₆₀ device we study is illustrated schematically in Fig. 1(a) where a C₆₀ molecule is bonded by two atomic scale Al metallic electrodes which extend to reservoirs far away where bias voltages \( \pm V_{l,r} \) are applied to the left (l) and right (r) electrodes, respectively. An additional gate voltage \( V_g \) may also be applied to a metallic gate capacitively coupled to the molecule. Due to the large number of atoms and complications such as the gate, the bias, the atomic electrodes (as opposed to jellium electrodes), and the presence of localized states, existing ab initio methods for analyzing quantum transport⁹⁻¹¹ cannot be applied. We have therefore developed an approach which combines nonequilibrium Green’s-function theory¹²,¹³ with pseudopotential real-space ab initio density-functional theory simulation techniques.¹⁴ It is worth noting that conventional ab initio density-functional methods solve problems for either finite systems such as an isolated molecule, or periodic systems consisting of supercells. In contrast, a typical device geometry [e.g., Fig. 1(a)], is neither isolated nor periodic, but is a system having open boundaries provided by long electrodes which maintain different chemical potentials due to external bias.

FIG. 1. (a) Schematic plot of the C₆₀ molecular device. (b) Contour plot of the equilibrium charge density. Note the perfect match across the boundaries between the scattering region and the electrodes.
Briefly, our technique is outlined as follows. We divide the long device system into three regions: left and right electrodes, and a scattering region [Fig. 1(a)]. The scattering region actually includes a portion of the semi-infinite electrodes. After density-functional theory iteration is completed (the total energy is converged to within $10^{-4}$ eV), this arrangement gives good bonding between the electrodes and the molecule, establishes a common Fermi level for the system, and ensures charge neutrality at equilibrium. We investigate situations away from the Coulomb blockade regime, as in the experiment of Ref. 1; this effect is not important here, due to the lack of any significant tunnel barriers between the C$_{60}$ and the electrodes. When the scattering region is large enough, the Kohn-Sham potential outside the scattering region is well screened, and therefore well approximated by a perfect “bulk” electrode environment which we obtain by a separate additional calculation. By setting the Kohn-Sham potential outside the scattering region to the bulk value, and matching the electrostatic potential at the boundary (including the gate), the infinite open boundary problem is reduced to the calculation of charge density inside the finite scattering region with the electrodes contribution accounted for by self-energies of the Green’s function (see below).

To perform our self-consistent density-functional analysis, we calculate the charge density from the density-matrix operator which is related to nonequilibrium Green’s functions, \[^{12,13,17}\]

$$\hat{\rho} = i \int_{-\infty}^{\infty} dE \, G^r(E) = i \int_{-\infty}^{\infty} dE \, G^R \Sigma^< \Sigma^A,$$

(1)

where \[^{12,13,17}\] $\Sigma^< = -2i \Sigma_{\alpha=\uparrow,\downarrow} f_{\alpha}(E; \mu_{\alpha}) \text{Im} \{ \Sigma_i^{E}(E; \mu_{\alpha}) \}$. $f_{\alpha}(E; \mu_{\alpha})$ are the distribution functions deep in electrodes with chemical potentials $\mu_{\alpha}$, assuming reservoirs to be at equilibrium and system at low temperature, where $\Theta$ is the step function. The retarded (and advanced) Green’s functions $G^r (G^A)$ of the system are calculated by direct matrix inversion where self-energies due to coupling to electrodes $(\Sigma_{\alpha,a})$ are obtained by extending the method discussed in detail in Ref. 18. With the charge density calculated from Eq. (1), we can evaluate the effective device potential $V_{\text{eff}}[\rho(r)]$ which consists of Hartree, exchange-correlation, atomic core, and any other external potentials. Using the boundary condition on the effective potential discussed above, $V_{\text{eff}}(r)$ is defined everywhere in space. It is therefore straightforward to construct the Hamiltonian matrix using an $s$, $p$ Fireball atomic orbital basis set. We use standard norm-conserving pseudopotentials to describe the atomic cores. The density-functional iteration is repeated until self-consistency, and current is calculated by integrating conductance $G(E)$ over energy with $G(E) = 4G_o \text{Tr}[ \text{Im} \Sigma_i^{E} ] G^R \text{Im} \Sigma_i^{E} G^A$, where $G_o = 2e^2/h$.

Figure 1(b) shows the equilibrium charge distribution along the middle cross section of the device at zero bias and gate voltages. The charge density in the electrodes is affected by the C$_{60}$, but this effect is well screened away from the molecule. Indeed, the charge-density contours match perfectly at the connections between the electrodes and the scattering region. The electronic structure of an isolated C$_{60}$ molecule is well known and our $ab$ initio calculation gives a highest occupied–lowest unoccupied molecular-orbital (HOMO-LUMO) gap of 1.77 eV, in excellent agreement with previous literature. The undoped C$_{60}$ is a semiconductor, but one can dope the solid and fill the LUMO state with up to six electrons. Importantly, for our device the open metallic electrodes provide natural doping through charge transfer. As a result we found that, in equilibrium, three extra electrons flow into the molecular region. This is a substantial charge transfer in order for the molecule to equilibrate with the electrodes, so that a common Fermi level is established. Experimentally it has been known that C$_{60}$ solid conducts best when doped with three electrons per C$_{60}$. This is because doping three electrons amounts to half-filling the LUMO. Our $ab$ initio analysis predicts, for the C$_{60}$ device, that the C$_{60}$ LUMO state is half-filled and we find an equilibrium conductance of $G(E_F)=2.2G_o$ at zero temperature. This value is very significant: without charge transfer we would expect a much smaller conductance due to the filled HOMO state and the substantial HOMO-LUMO gap of the isolated C$_{60}$.

In Fig. 2, we plot the equilibrium transmission eigenvalues of the device as a function of electron energy at two different gate voltages. At $V_g=0$, there are three transmission eigenvectors which contribute substantially at $E_F$ (the vertical line) to the equilibrium conductance $G=2.2G_o$. However, a gate voltage shifts the states near $E_F$ and changes the transmission channels significantly. This is shown in Fig. 2(b), where we see a conductance gap at $E_F$. Therefore, a gate potential can change electron conduction through this device significantly, producing field-induced molecular switching. We can understand the transport properties by projecting the scattering states of the device on to
the molecular orbitals of an isolated C$_{60}$. We found that scattering states near $E_F$ are over 90% HOMO or LUMO in “character,” indicating that other orbitals are less important for conduction in this device. In addition, we can classify each scattering state as being majority HOMO or majority LUMO. We find that majority HOMO states are almost pure HOMO ($>90\%$), while majority LUMO states are a HOMO-LUMO mixture ($\sim 30:70$). Specifically, the transmission eigenvectors of Fig. 2(a) are all LUMO-like, indicating that there are three electrons half-filling the LUMO state and contributing three conduction channels at equilibrium. In other words, the LUMO state is naturally aligned with $E_F$ due to charge transfer. On the other hand, a negative gate voltage can inhibit charge transfer, so that $E_F$ lies between the HOMO and LUMO states of the molecule. Indeed, we found that the scattering state corresponding to the left peak in Fig. 2(b) is HOMO-like, and that of the right peak is LUMO-like. In the absence of charge transfer, one would expect transmission properties similar to those in Fig. 2(b).

The above physical picture is further demonstrated in Fig. 3, which shows the equilibrium conductance $G$, the three individual transmission eigenvalues $T_i$ ($i = 1, 2, 3$), and the number of transferred charge $Q$ (inset) as functions of gate voltage $V_g$ at $E_F$. $G$ has a steplike behavior: each “step” is due to the depletion of a LUMO-like state. Only after charge transfer is completely inhibited do we obtain the conductance gap illustrated in Fig. 2(b), where $G$ becomes very small. Our result therefore indicates that charge transfer plays a crucial role, and changes the physical picture of electron conduction in this device qualitatively. The behavior of $G$ also has a clear correspondence with $T_i$ (the dotted lines with circles): as $V_g$ is scanned toward more negative values, $T_i$‘s are removed one by one.

Charge transfer also has very important implications for the $I$-$V$ curves, shown in Fig. 4. The current is plotted as a function of right bias $V_r$, fixing $V_l=0$. When $V_g=0$ the $I$-$V$ curve shows a clear metallic behavior. When $V_g \neq 0$, the C$_{60}$ device can change from a metal [Fig. 2(a)] to a semiconductor [Fig. 2(b)] with a conductance gap near zero bias. Therefore the gate potential can “switch” off the current, reflecting the transition of transmission eigenvalues from Figs. 2(a) to 2(b). This corresponds to an amplification factor of $\sim 20$.

The value of gate potential is nonuniversal, as it depends on the shape of the gate and dielectric medium surrounding the device. What is essential is to produce enough electric-field lines inside the molecular region so that the electrode-doped LUMO electrons are depleted from the molecular junction. For our system, a shift of $\sim 0.1$ eV is enough to generate switching. This is, however, a large shift, and it suggests that a sharp-shaped gate is perhaps necessary in an experimental setup; otherwise most field lines will be screened by the metallic electrodes. The predicted current is in the range of $\sim 10 \mu A$ at small bias voltages ($\sim 50$ mV). This is somewhat larger than the $\sim 4 \mu A$ measured for the electro-mechanic amplifier.$^{1,2}$

Our results have important implications, and provide a benchmark for semiempirical and other theories, such as those based on parametrized tight-binding models. The chemical potential difference between an isolated Al electrode and an isolated C$_{60}$ molecule is $\Delta = E_F^{\text{electrode}} - E_F^{C_{60}} \sim 0.19$ a.u. This provides a lot of uncertainty as how one should align the molecular orbitals to the Fermi level of the electrodes in a non-self-consistent calculation. Specifically, calculating $G(E_F^{\text{electrode}})$ without alignment gives 1.17$G_o$, much less than the correct result. Shifting levels of C$_{60}$ by adjusting a chemical potential so that global charge neutrality is obtained, we obtain 1.7$G_o$. Shifting levels so that three extra charges are inside the C$_{60}$ region, the result becomes 2.0$G_o$. Because we cannot know charge transfer in a non-self-consistent analysis, this result suggests that requiring global charge neutrality in a semiempirical calculation is the next best thing to do at equilibrium. In this regard, we note that there has been some practice for requiring local charge neutrality on each atom$^{27,28}$ in semiempirical calculations. Another interesting result we found is that there are many localized states in the molecular junction. At equilibrium, we find 96 bound states by integrating the density of states [Eq. (1)] from $-\infty$ to the propagating threshold of the electrodes. These localized states play an important role in establishing the effective potential $V_{\text{eff}}$, and must be included in the analysis.$^{29,30}$
In summary, our results suggest that charge-transfer doping induces a substantial conductance in a well-contacted molecular C$_{60}$ device. Essentially, charge-transfer doping aligns the LUMO states of the C$_{60}$ with the Fermi level of the electrodes, opening up three conductance channels and producing metallic I-V characteristics at equilibrium. A field effect provided by a gate potential can switch off the current by inhibiting charge transfer. This is very interesting from a device operation point of view, and provides a mechanism for molecular scale current switch, complementing the electromechanical operation principle explored in previous work.\(^1\)

\(^15\) The detailed numerical procedure will be published elsewhere; J. Taylor and H. Guo (unpublished).

\(^22\) For simplicity we have fixed the atomic positions. The electrode-molecule distance is kept at 1.06 Å for the results presented here. We have confirmed that there is no qualitative change in the results when this distance is varied, so long as bonding between electrodes and the molecule exists. An Al electrode is represented by a slab of Al oriented along the (100) plane with 18 atoms per unit cell. We have confirmed that doubling the electrode length (the portion included inside the scattering region) gives essentially the same result. The matching of the charge density contours [Fig. 1(b)] gives a strong confirmation of the numerical accuracy, as the boundary condition on the potential has generated a perfect match of the charge density.

\(^24\) The average gap value from the literature is 1.8 eV. See, for example, *Science of Fullerenes and Carbon Nanotubes* (Ref. 23), p. 458.

\(^25\) We do not expect exact agreement because of the different physical mechanisms for conduction. In addition, the C$_{60}$ in our device is very well contacted, which tends to give a larger current.

\(^26\) We have carried out the non-self-consistent calculation using the Harris functional.
