CONSTRAINING THE ORIGIN OF TeV PHOTONS FROM GAMMA-RAY BURSTS WITH DELAYED MeV–GeV EMISSION FORMED BY INTERACTION WITH COSMIC INFRARED/MICROWAVE BACKGROUND PHOTONS

X. Y. WANG,¹ ² K. S. CHENG,² Z. G. DAI,¹ and T. LU³

Received 2003 September 13; accepted 2003 November 17

ABSTRACT

It has been suggested that electromagnetic cascade of very high-energy gamma-rays from gamma-ray bursts (GRBs) in the infrared/microwave background can produce delayed MeV–GeV photons. This delay could be caused by the angular spreading effect of the scattered microwave photons or deflection of the secondary pairs due to the intergalactic magnetic field. Very high-energy TeV photons of GRBs could be produced by a few mechanisms including the proton-synchrotron radiation and electron inverse Compton emission from GRB internal shocks as well as external shocks. We suggest that the information provided by the delayed emission could give constraints on models for TeV gamma-rays. A more accurate calculation of the delayed time caused by the angular spreading effect is presented by considering recent observations of the extragalactic infrared background and the theoretical high-redshift infrared background. We also suggest that the dependence of the maximum time delay of scattered photons on their energies, if determined by future GLAST detector, could differentiate the two mechanisms causing the time delay.

Subject headings: diffuse radiation — gamma rays: bursts — magnetic fields

1. INTRODUCTION

Giga–electron volt emission from gamma-ray burst (GRB) sources is now considered a well-established fact (e.g., Sommer et al. 1994; Hurley et al. 1994) and there is also tentative evidence for TeV emission (e.g., Amenomori et al. 1996; Padilla et al. 1998). Recently, the Milagro group reported the detection of an excess of TeV gamma-rays above the background from one of the 54 BATSE GRBs (GRB 970417a) in the field of view of their detector, with a chance probability $\sim 1.5 \times 10^{-3}$ (Atkins et al. 2000). Poirier et al. (2003) reported suggestive evidence for sub-TeV gamma rays arriving in coincidence with GRBs. Although these observations were not claimed as firm detection, the production of TeV photons are also predicted by GRB theories. The emission mechanism for TeV photons includes electron inverse Compton (IC) emission and synchrotron emission from the protons accelerated by GRB shocks. These shocks could be internal shocks, external forward shocks, or external reverse shocks of GRBs. Such very high-energy photons at cosmological distance, however, may largely be absorbed by interacting with the cosmic infrared background radiation (CIB; e.g., Stecker, De Jager, & Salamon 1992; Madau & Phinney 1996). The IC scattering of the created $e^+e^-$ pairs off the cosmic microwave background (CMB) photons will produce delayed MeV–GeV emission (Cheng & Cheng 1996; Dai & Lu 2002). There are two likely mechanisms causing the time delay. One is the angular spreading effect of the secondary pairs, i.e., the scattered microwave photons deviate from the direction of the original TeV photons by an angle $\sim 1/\gamma$, where $\gamma$ is the Lorentz factor of the $e^+e^-$ pairs (Cheng & Cheng 1996; Dai & Lu 2002). Another mechanism is related to the deflection of the propagating direction of the pairs in the intergalactic magnetic field (IGMF), if this field is sufficiently strong (Plaga 1995).

Dai & Lu (2002) have discussed the spectrum and duration of the delayed emission, assuming that the high-energy primary photons ($E_\gamma > 300$ GeV)⁵ are produced by the electron IC emission in internal shocks. Recently, Guetta & Granot (2003) argued that the intrinsic cutoff energy of photons from internal shocks can hardly extend to $\gtrsim 100$ GeV for typical GRBs with peak energy in the BATSE energy range. Here we extend the work of Dai & Lu (2002) by considering that TeV photons could also come from external shocks and could be produced by proton-synchrotron radiation. We further suggest that the information provided by the delayed emission could constrain the emission mechanism of the TeV photons from GRBs and distinguish between the two mechanisms causing the time delay. We will also study the detectability of the delayed emission by the future GLAST detector.

In §5, we present three emission processes for TeV photons and the corresponding spectrum and calculate the cutoff energy for high-energy photons from external shocks due to $\gamma\gamma$ pair attenuation with softer photons. We find that the cutoff energy exceeds 10 TeV for typical parameters. In §3, we compare the spectra of the delayed emission for these three emission models of TeV photons and give a more accurate calculation of the delayed time caused by the angular spreading by considering recent observations of the extragalactic infrared background and the theoretical high-redshift infrared background. Then, in §4, we study the particular case of GRB 940217, from which delayed emission had already

⁴ The decay of $\pi^0$ produced in photo-meson interactions in internal (Waxman & Bahcall 1997) or external shocks (Waxman & Bahcall 2000; Dai & Lu 2001) of GRBs could also lead to production of very high-energy photons, but with characteristic energies higher than $10^{14}$ eV. So a low radiation efficiency of TeV photons is expected for this process.

⁵ Please note that here $E_\gamma$ is the gamma-ray energy at the rest frame of GRBs.
been detected by EGRET. Finally, we give the conclusions and discussions.

2. TeV EMISSION MODELS OF GAMMA-RAY BURSTS

GRBs are thought to be caused by the dissipation, through shocks, of the kinetic energy of a relativistically expanding fireball with a Lorentz factor $\Gamma_0 \sim 10^2$--$10^3$. The shocks could be either internal (Paczynski & Xu 1994; Rees & Mészáros 1994) due to collisions between fireball shells or external (Rees & Mészáros 1992; Dermer, Böttcher, & Chiang 1999) due to the interaction of the fireball with the external medium. When the relativistic ejecta encounters the external medium, a relativistic forward shock expands into the external medium, and a reverse shock moves into and heats the fireball ejecta (Sari & Piran 1999). Very high-energy photons can be produced by electron IC and proton–synchrotron emission in both internal shocks and external shocks. There should be a cutoff in the high-energy gamma-ray spectrum due to the internal absorption of high-energy gamma rays by pair-production in GRBs. (e.g., Baring & Harding 1997; Totani 1999; Lithwick & Sari 2001) Recently, Guetta & Granot (2003) argue that a high cutoff energy for emission from internal shocks needs large value of the initial Lorentz factor $\Gamma_0$ or variability time $t_r$, but at the same time, they imply lower values of the peak energy $E_p$ of the synchrotron emission. So they conclude that TeV photons from internal shocks can hardly reconcile with typical GRBs but may be related with X-ray flashes. However, this conclusion is dependent on the assumption that the observed GRB spectral peak is due to characteristic synchrotron photon energy, and this is not completely confirmed. For example, Totani (1999) pointed out that efficient pair-production in GRBs may affect the peak of GRB spectrum around MeV. We note that TeV photons could also come from external shocks and the cutoff energy may be significantly increased because external shocks have much larger sizes than those of internal shocks. Below we will first estimate the cutoff energy for external shocks.

We adopt an analytical approach similar to the one developed for internal shocks by Lithwick & Sari (2001) and apply to afterglows by Zhang & Mészáros (2001), but we here apply to the initial phase of external shocks. The attenuation optical depth of high-energy photons with softer photons is (Lithwick & Sari 2001)

$$\tau_{\gamma\gamma} = (11/180)\sigma_T N(>E_{\text{an}})/4\pi r_{\text{dec}}^2,$$

where $N(>E_{\text{an}})$ is the total photon number with energy above the attenuation threshold energy $E_{\text{an}}$, $r_{\text{dec}}$ is the deceleration radius at which external shocks take place, and $\sigma_T$ is the Thomson cross section. Like Zhang & Mészáros (2001), we assume that the emission spectrum around $E_{\text{em}} = h\nu_{\text{em}}$ is $L(\nu) = F_\nu 4\pi D^2/(1+z) \propto \nu^{-\delta}$, then the optical depth is

$$\tau_{\gamma\gamma} = \left[(11/180)\sigma_T F_\nu (\nu_{\text{an}}) d_L^2ight]/4\pi \nu^2 h\delta_{\text{dec}},$$

where $d_L$ is the source distance, $z$ is the redshift of the source, $h$ is Planck’s constant, and $t_{\text{dec}} = 10E_{\text{53}} n_0^{-1} (\Gamma_0/300)^{-5/2}$ s

is the deceleration timescale of the GRB ejecta. For primary photons in the TeV band, the attenuation threshold energy is $E_{\text{an}} = h\nu_{\text{an}} = 20(\Gamma_0/300)^2 (E_p/1 \text{ TeV})^{-1}$ keV. At $h\nu \sim 10$ keV, the emission is dominated by the electron synchrotron radiation from the external forward shocks (see Fig. 2 in Wang, Dai, & Lu 2001). The two characteristic frequencies and the peak flux of the synchrotron spectrum of the external forward shocks are given by

$${\nu}_c^{\text{fs}} = \frac{4 \times 10^{20}}{(p - 2)^2} \left(\frac{\epsilon_e}{0.5}\right)^2 \frac{1}{\epsilon_B - 2} \left(\frac{\Gamma_0}{300}\right)^4 n_0^{1/2} \text{Hz},$$

$${\nu}_e^{\text{fs}} = \frac{10^{17}}{(Y + 1)^2} E_{\text{53}}^{-1/2} \epsilon_{B,-2}^{-3/2} n_0^{-1} \left(\frac{t_{\text{dec}}}{10 \text{ s}}\right)^{-1/2} \text{Hz},$$

and

$$F_{\nu}^{\text{fs}} = 26D_{\text{L,26}}^{-2} E_{\text{53}}^{-1/2} \epsilon_{B,-2}^{-1} n_0^{-1/2} \text{mJy},$$

respectively, where $\epsilon_e$ and $\epsilon_B$ are the fractions of the shock energy carried by electrons and magnetic field, respectively, $Y \simeq (\epsilon_e/\epsilon_B)^{1/2}$ is the Compton factor, and $n$ is the number density of the external medium. We use the usual notation $a = 10^a a_0$ throughout the paper. Generally, we have $\nu^{\text{fs}}_e < \nu_{\text{an}} < \nu^{\text{fs}}_c$, so

$$F_{\nu}(\nu_{\text{an}}) = \left(\frac{\nu_{\text{an}}}{\nu^{\text{fs}}_c}\right)^{-1} F_{\nu}^{\text{fs}} = 3.8(Y + 1)^{-1} \left(\frac{\Gamma_0}{300}\right)^{-1} \times \left(\frac{\epsilon_e}{c} \epsilon_{B,-2}^{-1/2} n_0^{1/2} \frac{t_{\text{dec}}}{10 \text{ s}} \frac{E_{\gamma}}{1 \text{ TeV}}\right)^{1/2} \text{mJy}.$$

From equation (1), finally we get the cutoff energy where $\tau_{\gamma\gamma} = 1$,

$$E_{\text{cut}} \sim 40 \left(\frac{\Gamma_0}{300}\right)^{10/3} E_{\text{53}}^{-2/3} \epsilon_{B,-2}^{-1/2} n_0^{-5/6} \text{ TeV}.$$
synchrotron emission has been discussed by a number of authors (Vietri 1997; Böttcher & Dermer 1998; Totani 1998a, 1998b). For external shocks, the postshock magnetic field is 

\[ B = (32\pi\epsilon_g\Gamma_0^2n_m c^2)^{1/2} \]

and the energy of the synchrotron photons is given by

\[ E_{\text{syn}} = \frac{\Gamma_p\epsilon_{eh}B}{2\pi m_pc} = 3 \text{ TeV} E_{p,21}^{1/2}n_0^{1/2}, \]  

where \( \Gamma_p \) and \( E_p \) are, respectively, the Lorentz factor and energy of the protons. Totani (1998a, 1998b) argues that the protons can be accelerated up to \( 10^{20} - 10^{21} \) eV for \( \Gamma_0 = 100 - 1000 \), so we expect \( E_{p,21} \) can extend to TeV band for \( \epsilon_{gh} \sim 1 \). The energy spectrum from proton-synchrotron radiation is \( \nu F_\nu \propto \nu^{(3-p)/2} \), which is distinct from the electron IC emission spectrum we discussed above.

### 3. Spectrum, Duration, and Intensity of the Delayed Emission

#### 3.1. Spectrum of the Delayed Emission

Tera–electron volt gamma-rays emitted from extragalactic sources may collide with diffuse cosmic infrared background (CIB) photons, leading to secondary \( e^+e^- \) pairs. The pair production optical depth \( \tau_{\gamma\gamma} \) depends on the spectral energy distribution and the intensity of the CIB, which is currently not well known. Because of the high redshift of cosmological GRB sources, \( \tau_{\gamma\gamma} \) also depends on the evolution of the CIB with the redshift, which also remains uncertain. Despite these uncertainties, calculations based on the theoretical models (e.g., De Jager & Stecker 2002; Aharonian et al. 2002) of CIB and modeling of observations of the TeV blazar H1426+428 (Aharonian et al. 2002; Costamante et al. 2003) show that \( \tau_{\gamma\gamma} \) is significantly larger than unity for photons with \( \epsilon_\gamma \gtrsim 500 \text{ GeV} \) from extragalactic GRBs with redshift \( z \gtrsim 0.3 \) (also see Totani & Takeuchi 2002, in which a somewhat lower optical depth is obtained). On the other hand, \( \tau_{\gamma\gamma} \) from the synchrotron radiation of protons or electron IC emission may extend to a few TeV. So we here choose to study the primary very high-energy photons with energy in the range of 0.5–5 TeV that are almost totally absorbed by the CIB photons. We assume a general form for the energy spectrum of the primary high-energy emission at TeV band: \( \nu L_\nu \propto \nu^{-\alpha} \). The photon spectrum is accordingly \( N_\nu \propto \nu^{-(\alpha+2)} \), and the spectrum of the secondary pairs is then \( dN_\gamma/d\gamma \propto \gamma^{-(\alpha+2)} \). The secondary pairs would boost the CMB photons to higher energy by IC scattering. The scattered photons (or delayed photons) will have a characteristic energy

\[ \epsilon = \frac{4}{3} \gamma_{\text{e}}^2(\epsilon) = 0.8 \left( \frac{\epsilon_{\gamma}}{1 \text{ TeV}} \right)^2 \text{ GeV}, \]  

where \( \epsilon_{\gamma} = 2.7kT_{\text{CMB}} \) is the mean energy of the CMB photons and \( \gamma_{\text{e}} \) is the Lorentz factor of the secondary pairs resulting from a primary photon with energy \( \epsilon_\gamma \). So for \( \epsilon_\gamma \in [0.5, 5] \text{ TeV} \), the energies of the scattered photons are in the range 200 MeV–20 GeV correspondingly.

The time integrated spectrum of the scattered CMB photons should be

\[ \frac{dN_\gamma}{d\epsilon} \propto \epsilon^{-(\alpha+4)/2} \]  

(Blumenthal & Gould 1970; Dai & Lu 2002). Strictly speaking, this form holds only when all the TeV photons are absorbed locally, i.e., their production mean free path \( R_{\text{pair}} \) should be much smaller than the luminosity distance of the sources; otherwise, TeV photons of different energy may be absorbed at different redshift \( z_{\text{pair}} \), causing the observed delayed photons energy shifted from equation (9) by a factor \( 1 - [1 + 2z_{\text{pair}}]/(1 + 2z) \). But, for the calculated values of \( R_{\text{pair}} \) in the next subsection, we find that this factor is within 15% and so this form holds with a good approximation. It is important to note that if we choose the part of TeV photons that are totally absorbed locally, the spectrum of the delayed emission is independent of the poorly known CIB. For three different TeV models, the spectra of the scattered (delayed) emission are different, as presented in Table 1. From Table 1, we can see that the spectra of the delayed emission are significantly different from each other and we can therefore use this difference to constrain the emission mechanism of the primary TeV photons.

#### 3.2. The Duration of the Delayed Emission

The duration of the scattered CMB photons should be the maximum of three timescales: \( \tau_1 \), the observed IC cooling lifetime of the secondary electrons; \( \tau_2 \), the timescale caused by the deflection of the electrons due to the IGMF; and \( \tau_3 \), the

Note.—The quantity \(-\alpha + 2 \) \([dN_\gamma/d\epsilon_e] \propto \epsilon_e^{\alpha+2} \) is the spectral index of the photon spectrum of the primary TeV photons, and \(-\beta \) \([dN_\gamma/d\epsilon] \propto \epsilon^{-\beta} \) is the spectral index of the photon spectrum of the delayed MeV–GeV photons.
angular spreading time (Dai & Lu 2002; Dai et al. 2002). Dai & Lu (2002) have derived
\[ \tau_1 = \frac{3m_ec}{8\gamma^4 \sigma_T u_{\text{CMB}}} = 37 \left( \frac{E}{1 \text{ TeV}} \right)^{-3} \tau = 37 \left( \frac{\epsilon}{0.8 \text{ GeV}} \right)^{-3/2} \text{s}, \]
(11)

where \( u_{\text{CMB}} \) is the energy density of the CMB photons and \( \gamma_r \) is the Lorentz factor of the secondary electrons, and it relates to the energy of the primary TeV photons by \( \gamma_r = 10^6 (E_c/1 \text{TeV}) \). The timescale caused by the deflection of the electrons due to the IGMF is given by
\[ \tau_2 = 6.1 \times 10^3 \left( \frac{E}{1 \text{ TeV}} \right)^{-5} \left( \frac{B_{\text{IGMF}}}{10^{-20} \text{ G}} \right)^2 \tau = 6.1 \times 10^3 \left( \frac{\epsilon}{0.8 \text{ GeV}} \right)^{-5/2} \left( \frac{B_{\text{IGMF}}}{10^{-20} \text{ G}} \right)^2 \text{s}. \]
(12)

To know \( \tau_3 \), we must know the mean free path \( R_{\text{pair}} \) of the very high-energy photons in the extragalactic IR background, which depends on the intensity of the IR background. Electron-positron pair creation due to the interaction of a \( \gamma \)-ray photon of energy \( E_\gamma \), with a softer photon of energy \( \epsilon \) can take place provided that \( E_\gamma (1 - \cos \theta) \geq 2(m_ec^2)^2 \), where \( \theta \) is the encounter angle of the two photons. For a fixed \( \gamma \)-ray energy \( E_\gamma \), the pair production cross section \( \sigma \) rises steeply from the threshold \( \epsilon_{\text{th}} \), has a maximum value equal to 0.26\( \sigma_T \) at \( \epsilon = 2m_e^2c^4/E_\gamma \) and then falls off as \( \epsilon^{-1} \) for \( \epsilon > \epsilon_{\text{th}} \). Because of the peaked cross section, collisions will preferentially take place between \( \gamma \)-ray photons of energy \( E_\gamma \), and soft photons with energy \( \sim 2m_e^2c^4/E_\gamma \). So for \( E_\gamma \) in the range of 0.5–5 TeV, the wavelengths of the softer photons with which pair production preferentially takes place are in the range 1.2–12 \( \mu \)m.

Since GRBs are at cosmological distances and CIB evolves with the redshift (Salamon & Stecker 1998), \( R_{\text{pair}} \) should depend on the redshift of the GRBs. For simplicity, we will discuss three representative cases with (a) \( z = 0.3 \), (b) \( z = 1 \), and (c) \( z = 3 \).

Case a (\( z = 0.3 \)).—It can be assumed that CIB is in place by a time corresponding to \( z = 0.3 \), so the CIB photon number density at \( z = 0.3 \) is \( (1 + z)^3 \) higher than the value at \( z = 0 \). Observations of CIB show that its spectral energy distribution has a peak around 1–2 \( \mu \)m and a valley at mid-IR band. In the wavelength range of \( \sim 1.2–12 \mu \)m that we are interested in, the number densities of the CIB photons can be approximately shaped by \( \bar{n}(\epsilon) \propto \epsilon^{-k_1} \) with \( k_1 \approx 0 \) (Coppi & Aharonian 1999; Aharonian et al. 2002), which results in a nearly constant \( R_{\text{pair}} \). The observed CIB flux \( J_\nu \) at 2.2 \( \mu \)m is of the order of \( \sim 10 \text{ nW m}^{-2} \text{ sr}^{-1} \) (Wright & Johnson 2001; Wright 2003), so the number density of the CIB photons at \( z = 0 \) is
\[ \bar{n}(\epsilon) \big|_{\lambda = 2.2 \mu m} = \frac{4\pi J_\nu}{c \epsilon} = 0.45 \times 10^{-2} \text{ cm}^{-3}. \]
(13)

Then we obtain the mean free path for TeV photons at \( z = 0.3 \):
\[ R_{\text{pair}} = \frac{1}{0.26\sigma_T \bar{n}(\epsilon) (1 + z)^3} = 0.55 \times 10^{27} \left( \frac{E_\gamma}{1 \text{ TeV}} \right)^{-k_1} \text{ cm}, \]
(14)

and
\[ \tau_3(z = 0.3) = \frac{R_{\text{pair}}}{2\gamma^2 \epsilon} = 1.0 \times 10^4 \left( \frac{E_\gamma}{1 \text{ TeV}} \right)^{-2-k_1} \text{s} = 1.0 \times 10^4 \left( \frac{\epsilon}{0.8 \text{ GeV}} \right)^{-1-k_1/2} \text{s}. \]
(15)

Case b (\( z = 1 \)).—Salamon & Stecker (1998) have derived the intergalactic comoving radiation energy density as a function of wavelength in the range \( 10^{-2}–2.5 \mu \)m for several fixed redshifts by considering the stellar emissivity with and without metallicity. We shall assume that the power-law form \( n(\epsilon) \propto \epsilon^{-k_2} \) also holds in the range 1.2–12 \( \mu \)m for \( z = 1 \), but the intensity of CIB is lower than that at \( z = 0 \), according to the calculation result of Salamon & Stecker (1998). At \( \lambda = 2.2 \mu \)m, the intergalactic comoving radiation energy density \( U_\nu \) at \( z = 1 \) is about \( 9 \times 10^{-30} \text{ ergs Hz}^{-1} \text{ cm}^{-3} \), so
\[ n(\epsilon, z = 1) = \frac{U_\nu}{h} = 1.4 \times 10^{-3} \left( \frac{\lambda}{2.2 \mu \text{m}} \right)^{k_2}. \]
(16)

Finally, we obtain \( R_{\text{pair}} \) and the delay time \( \tau_3 \) for bursts at \( z = 1 \):
\[ R_{\text{pair}} = \frac{1}{0.26\sigma_T n(\epsilon, z = 1) \epsilon} = 4 \times 10^{27} \left( \frac{E_\gamma}{1 \text{ TeV}} \right)^{-k_2} \text{ cm}, \]
(17)
\[ \tau_3(z = 1) = 6.67 \times 10^4 \left( \frac{E_\gamma}{1 \text{ TeV}} \right)^{-2-k_2} \text{s} = 6.67 \times 10^4 \left( \frac{\epsilon}{0.8 \text{ GeV}} \right)^{-1-k_1/2} \text{s}. \]
(18)

Case c (\( z = 3 \)).—The CIB radiation energy density is even lower. At \( \lambda = 2.2 \mu \)m, \( U_\nu \) is about \( 3 \times 10^{-30} \text{ ergs Hz}^{-1} \text{ cm}^{-3} \). So
\[ \tau_3(z = 3) = 2.2 \times 10^5 \left( \frac{E_\gamma}{1 \text{ TeV}} \right)^{-k_1} \text{s} = 2.2 \times 10^5 \left( \frac{\epsilon}{0.8 \text{ GeV}} \right)^{-1-k_1/2} \text{s}, \]
(19)

where \( n(\epsilon) \propto \epsilon^{-k_3} \) (\( \lambda = 1.2–12 \mu \)m) for CIB at \( z = 3 \). If we also consider the time dilation due to redshift, the delay time is even longer by a factor of \( 1 + z \).

To know the values of \( k_2 \) and \( k_3 \) in the range \( \lambda = 1.2–12 \mu \)m, we need to know the intergalactic comoving radiation energy density beyond \( \lambda = 2.5 \mu \)m (Salamon & Stecker 1998). But we expect that the absolute value of \( k_2 \) or \( k_3 \) is small, since they reflect the characteristic shape of the starlight spectrum, which in the wavelength band between 1 and several microns behaves as \( \nu I(\nu) \propto \lambda^3 \) with \( \beta \approx -1 \).

Comparing these three timescales, we know that the observed IC life time \( \tau_1 \) is always much smaller than the other two timescales and therefore not related to the delay time. The time \( \tau \) may be comparable to \( \tau_2 \) at \( \epsilon = 0.8 \text{ GeV} \) if \( B_{\text{IGMF}} \sim 3 \times 10^{-20} \text{ G} \) for bursts at \( z \approx 1 \). By now, very little is known about the IGMF. To interpret the observed \( \sim \mu \)G magnetic fields in galaxies and X-ray clusters, the seed fields required in dynamo theories could be as low as \( 10^{-20} \text{ G} \) (Kulsrud et al. 1997;
Kulsrud 1999). Theoretical calculation of primordial magnetic fields show that these fields could be of order $10^{-20}$ G or even as low as $10^{-29}$ G, generated during the cosmological QCD or electroweak phase transition, respectively (Sigl, Olinto, & Jedamzik 1997). So, if we know which timescale is responsible for the delay time, we can constrain the strength of the IGMF.

A way to distinguish which mechanism causes the time delay $\Delta t$ is to examine the dependence of the maximum time delay $\Delta t(\varepsilon)$ of the scattered photons on their energy $\varepsilon$. From the definition of $\tau_2$ (eq. [12]) or $\tau_3$ (eqs. [15], [18], or [19]), we can obtain the dependence of the maximum time delay on photon energy. If the delay time is dominated by $\tau_2$, $\Delta t(\varepsilon) \propto \varepsilon^{-5/2}$, while $\Delta t(\varepsilon) \propto \varepsilon^{-(1+\alpha)}$ if it is dominated by $\tau_3$, where $\alpha = 0, k_1/2, k_2/2$ for bursts at $z = 0.3, 1, 3$, respectively.

Regardless of which of the two timescales is responsible for the time delay, from the expressions of $\tau_2$ and $\tau_3$, we know that softer photons tend to have larger amounts of delay. Another feature characteristic of our model for the delayed emission is that the flux of the delayed emission is roughly a constant over the whole duration. These may be used to tell our model from other models for the delayed emission from GRBs. For example, Zhang & Meszaros (2001) proposed that the electron IC emission from afterglow shocks could produce a delayed GeV component. But in their model, the GeV flux rises first to a peak and then declines in a power-law manner as $F_\gamma \propto t^{(11-9p)/8}$ (Zhang & Meszaros 2001).

3.3. Intensity of the Delayed Emission

We assume that the burst energy in the TeV energy range from $\varepsilon_1 = h\nu_1 = 0.5$ TeV to $\varepsilon_2 = h\nu_2 = 5$ TeV is a fraction $f$ of the burst energy in the BATSE energy range $E_B$, i.e.,

$$\int_{\varepsilon_1}^{\varepsilon_2} \frac{dN_\varepsilon}{d\varepsilon} = \int_{\nu_1}^{\nu_2} L_\nu d\nu = f E_B,$$

where $L_\nu$ is the luminosity per frequency and $\Delta t$ is the duration of the primary TeV emission, which is considered to be comparable to the prompt GRB duration in the BATSE band.

The energy of the primary photons from $\nu_1$ to $\nu_2$ is essentially redistributed to the scattered photons from $\varepsilon_1 = 200$ MeV to $\varepsilon_2 = 20$ GeV, i.e.,

$$\int_{\varepsilon_1}^{\varepsilon_2} \frac{dN_\varepsilon}{d\varepsilon} = \int_{\nu_1}^{\nu_2} L_\nu d\nu = f E_B. \quad (20)$$

So the observed, time integrated (over the total duration) differential energy spectrum is

$$\varepsilon^{-2} \frac{dN_\varepsilon}{d\varepsilon} \Delta t = \frac{\alpha}{2[1 - (\nu_2/\nu_1)^{\alpha'}]} \frac{f E_B}{4\pi d_L^2} \left( \frac{\varepsilon}{\varepsilon_1} \right)^{-\alpha/2}$$

$$= f_1 f \frac{E_B}{4\pi d_L^2} \left( \frac{\varepsilon}{\varepsilon_1} \right)^{-\alpha/2}$$

$$= 6 \times 10^{-7} \cdot 11^{-\alpha/2} \left( \frac{f_1}{0.25} \right)$$

$$\times f_2 E_{B,53} d_L^{-2} \left( \frac{\varepsilon}{0.8 \text{ GeV}} \right)^{-\alpha/2} \text{ ergs cm}^{-2}, \quad (21)$$

where $f_1 = \alpha \{ 2 [1 - (\nu_2/\nu_1)^{\alpha'}] \}^{-1}$ is, respectively, 0.13, 0.25, and 0.85 for three kinds of TeV spectrum for $p = 2.2$. The fraction $f$ of the burst energy in the TeV band is an unknown factor and may depend on the emission model and many unknown parameters like $\varepsilon_e$ and $\varepsilon_B$. For the model of the IC emission from the reverse shocks, we estimate $f \sim 0.01$ for typical shock parameters (see Fig. 2 in Wang et al. 2001), which is consistent with the observational result that the energy in the observed delayed emission from GRB 940217 is about a factor of 0.01 of the burst energy in the BATSE range.

The EGRET detector has fluence threshold of $\sim 2.1 \times 10^{-6}$ ergs cm$^{-2}$ for a short integration time regime ($t < 1.7 \times 10^5$ s) and of $\sim 2.1 \times 10^{-6}$ ergs cm$^{-2}$ (for $t \approx 1.7 \times 10^3$ s$^{1/2}$) for long-term observations. Therefore, EGRET could detect delayed GeV emission only from strong GRBs, such as GRB 940217. However, the future detector GLAST is much more sensitive. The fluence threshold for GLAST is roughly $\sim 4 \times 10^{-7}/(t/50^5)$ ergs cm$^{-2}$ for a long integration time regime (exposure time $t \geq 10^5$ s) and $\sim 4 \times 10^{-7}$ ergs cm$^{-2}$ for a short integration time (Gehrels & Michelson 1999; Zhang & Meszaros 2001). So we expect that GLAST could detect delayed emission from typical GRBs with $E_B = 10^{53}$ ergs at $d_L = 10^{28}$ cm.

4. GRB 940217

GRB 940217 is a very strong burst with a total fluence above 20 keV of $\sim 6.6 \pm 2.7 \times 10^{-4}$ ergs cm$^{-2}$ and a duration of $\sim 180$ s in the BATSE range (Hurley et al. 1994). It has the third largest fluence of $\sim 800$ BATSE bursts up to the detection time of this burst. During the period of the low-energy emission, i.e., the first $\sim 180$ s, EGRET detected 10 photons with energies ranging from a few tens of MeV to a few GeV, and the fluence in this range is $\sim 2 \times 10^{-3}$ ergs cm$^{-2}$. Most strikingly, an additional 18 high-energy photons were recorded for $\sim 5400$ s following this, including an 18 GeV photon and other 36–137 MeV photons. The fluence of the delayed emission was measured to be $7 \times 10^{-6}$ ergs cm$^{-2}$ in the energy range 30 MeV–3 GeV. Among many models for delayed high-energy emission from GRBs (e.g., Meszaros & Rees 1994; Katz 1994; Plaga 1995; Totani 1998a, 1998b; Wang, Dai, & Lu 2002), one is that the delayed emission is the result of the electromagnetic cascade of the TeV photons and the inverse Compton scattering of the CMB radiation (Cheng & Cheng 1996).

Although this model suggests that soft photons tend to have larger amounts of delay time, a very long observation time is needed to detect this effect for delayed photons with energy $\lesssim 100$ MeV, as shown by expressions of $\tau_3$. For GRB 940217, the lack of high-energy photons within 36–137 MeV should occur at around $10^{55}$ s after the keV burst, while the observation of EGRET takes only $\sim 5000$ s. Thus, no correlation between time delay and photon energy could be found in the EGRET observations.

In this model, the 36–137 MeV photons should come from the cascade process of photons with energies $\varepsilon_2 < 0.5$ TeV. Since this part of high-energy photons may not be totally absorbed by IR photons, especially if this burst is at a low redshift, we get $f \geq 0.01$ for this burst. Up to the detection time of GRB 940217, EGRET has had some exposure to about 150 BATSE bursts (Hurley et al. 1994). Since GRB 940217 was the third strongest one of $\sim 800$ BATSE bursts and had a fluence of $(6.6 \pm 2.7) \times 10^{-4}$ ergs cm$^{-2}$, we estimate that only $\sim 1$ burst with fluence $F \gtrsim 2 \times 10^{-4}$ ergs cm$^{-2}$ had been exposed by EGRET. If $f \approx 0.01$, then only $\sim 1$ burst will have delayed emission sufficiently strong to be detected by EGRET, which is consistent with the lone detection of the delayed emission from GRBs by EGRET.

In the energy range $\varepsilon = 200$ MeV–20 GeV, there is only one delayed photon detected from GRB 940217, and therefore we have no reliable photon spectrum for the delayed emission of
this energy range. Below this energy, the delayed photon spectrum may deviate from the form equation (10), as the original very high-energy photons corresponding to this part of delayed emission may be partially absorbed by the CIB. Moreover, the expected theoretical spectrum (eq. [10]) is a time integrated spectrum over the whole duration of the delayed emission, while GRB 940217 was observed in a limited time. So we could not constrain the origin of its TeV photons by comparing the form of equation (10) with the photon spectrum of the delayed emission from GRB 940217, although a numerical approach taking account of the gamma-ray absorption effect might be feasible. However, we expect that this method has a promising prospect in the future GLAST era because of the significantly increased sensitivity of this detector, with the delayed emission detected from many more GRBs and the spectrum of photons $\epsilon \gtrsim 200$ MeV well determined.

5. SUMMARY

In previous papers (Cheng & Cheng 1996; Dai & Lu 2002), we have suggested that the very high-energy photons from cosmological GRBs may collide with cosmic IR background photons, leading to electron/positron pair production. Inverse Compton scattering of the pairs off CMB photons will produce delayed MeV–GeV emission. In this paper, we extend our previous works by the following points:

1. We suggest that TeV photons could also come from GRB external shocks. Compared with internal shocks, TeV photons from external shocks suffer little attenuation due to pair production with softer photons in the bursts.

2. There are a few emission models suggested for the TeV photons from GRBs, such as the proton-synchrotron radiation, the electron IC emission from external reverse shocks, and electron IC emission from intern shocks or external forward shocks. In this paper, we suggest that the spectrum of the delayed emission resulted from the TeV photons that were totally absorbed locally by the intergalactic IR background radiation could help to constrain the emission model of TeV photons from GRBs. Because this part of TeV photons are absorbed locally, the spectrum of the delayed emission is independent of the poorly known CIB. Since our treatment here is mainly analytic, a further numerical study to confirm this idea might be useful and necessary.

3. The time delay could be caused by the angular spreading effect of the scattered microwave photons or deflection of the secondary pairs due to IGMF. We present a more accurate calculation of the delay time caused by the angular spreading effect of the secondary electrons by considering recent observations of the extragalactic IR background and the theoretical prediction of the high-redshift IR background. By examining the dependence of the delay time on the photon energy, i.e., $\Delta t(\epsilon) \propto \epsilon^{-\delta}$, one can tell which of the two timescales is responsible for the delay time. For the delay time caused by the angular spreading effect, $\delta \approx 1$, while $\delta = 2.5$ otherwise.

Finally, we would like to point out that this model predicts a roughly constant flux for the delayed emission over the whole delay time and that soft photons tend to have larger amounts of delay, which constitute distinguished features to differentiate our model from other models.
