DESIGN AND MULTIPLIERLESS IMPLEMENTATION OF TWO-CHANNEL
BIORTHOGONAL IIR FILTER BANKS WITH LOW SYSTEM DELAY

J. S. Mao*, W.-S. Lu*, S. C. Chan†, and A. Antoniou∗

ABSTRACT
An efficient method for the design of low-delay two-channel, perfect
reconstruction IIR filter banks is proposed. The design problem
is formulated in terms of minimax designs of a general stable
IIR filter that can be obtained using semidefinite programming and
an FIR filter that can be obtained using the Remez exchange algo-
rithm. A multiplierless implementation on this filter bank is also
proposed and investigated.

1. INTRODUCTION
Low system delay is often desired for filter banks used in subband
coding, subband adaptive filtering, and many other applications
[1-3]. An interesting problem formulation that can be used for the
design of low-delay filter banks was proposed by Kim and Ansari
in [4] and developed further by Phoong, Kim, Vaidyanathan, and
Ansari in [5]. This formulation entails two independent func-
tions of , a( ) and ( ), that can be chosen to satisfy spec-
ified frequency-domain requirements while maintaining the perfect
reconstruction property (PR). More recent work on this type of
filter bank includes the method in [6] where a( ) and ( ) are
rational functions of that represent IIR filters and the method in
[7] where both a( ) and ( ) are polynomials in that repre-
sent nonlinear-phase FIR filters. In this paper, we use the formu-
lization in [4][5] to design low-delay filter banks but chose a( )
to be a polynomial in that represents a linear-phase FIR fil-
ter and ( ) to be a rational function of that represents an IIR
filter. Thus a( ) can be obtained by designing the FIR filter us-
ing the Remez exchange algorithm whereas ( ) can be obtained
by designing the corresponding IIR filter by using semidefinite
programming (SDP). Computer simulations demonstrate that the
proposed method yields satisfactory designs in terms of transition
width, stopband attenuation, and implementation complexity com-
pared with several existing methods. A multiplierless implementa-
tion of such IIR filter bank is also proposed.

2. DESIGN OF IIR ANALYSIS FILTER BANK
2.1. Lowpass Analysis Filter
Consider the 2-channel biorthogonal maximally decimated filter
bank shown in Fig. 1 where the analysis lowpass filter H0 and high-
pass filter H1 are characterized by:

\[ H_0(z) = \frac{1}{2} \left[ z^{-2N} + z^{-1} \beta(z^2) \right] \]  \hspace{1cm} (1a)

\[ H_1(z) = -\alpha(z^2)H_0(z) + z^{-2N-1} \]  \hspace{1cm} (1b)

respectively, function \( \alpha(z) \) is a polynomial in \( z^{-1} \) and \( \beta(z) \) is a
rational function in \( z \). The transfer functions of the synthesis filters
are given by \( G_0(z) = -H_1(-z) \) and \( G_1(z) = H_0(-z) \). A filter
bank of this type is known to have the perfect reconstruction (PR)
property regardless of the choices of \( \alpha(z) \) and \( \beta(z) \) [4][5]. The
formula of \( H_0(z) \) in (1a) suggests that if we design a lowpass filter
represented by \( \beta(z) \) with passband \([0,2\omega_p]\) and passband group
delay \( N - \frac{1}{2} \), then \( H_0 \) will be a lowpass filter with passband \([0,\omega_p]\)
and passband group delay \( 2N \) [5].

Let us assume that \( \beta(z) \) is the transfer function of an IIR filter of
the form

\[ \beta(z) = \frac{b(z)}{z^n-d(z)} = \frac{\sum_{i=0}^{n} b_i z^{-i}}{\sum_{i=0}^{m} d_i z^{-i}} \]

By formulating an error function and minimizing it using SDP, \( \beta(z) \) can be determined. Assuming that the sampling frequency
is \( 2\pi \), an error function can be defined as

\[ E_0(\omega) = \beta(\varepsilon^{j\omega}) - \beta_0(\omega) \]  \hspace{1cm} (2)

where \( \beta_0(\omega) \) is the desired frequency response of the IIR filter and is equal to \( \varepsilon^{-j\omega(N-1/2)} \) for \( \omega \in [0,2\omega_p] \) and zero elsewhere. An
approximation for \( \beta(z) \) can be obtained by solving the minimization
problem

\[ \text{minimize } \delta \]  \hspace{1cm} (3a)

subject to:

\[ \frac{W_2(\omega)}{|d_{k-1}(\omega)|^2} |b(\omega) - d(\omega)\beta_0(\omega)|^2 \leq \delta \]  \hspace{1cm} (3b)

for \( \omega \in [0,2\omega_p] \)

\[ d(z) \neq 0 \text{ for } |z| \geq 1 \]  \hspace{1cm} (3c)

where \( \delta = \max |E_0(\omega)| \), denotes the denominator poly-
nomial \( d(z) \) obtained in the \( (k-1) \)th iteration, \( W_2(\omega) \geq 0 \) is a
weighting function, and the stability of the IIR filter is assured by
the constraint in (3c). Now if \( \mathbf{x} = [\delta \ b \ d]^T \) with \( b = [b_0 \cdots b_n] \)
and \( d = [d_0 \cdots d_m] \), then the constraint in (3b) is equivalent to

\[ \mathbf{H} = \begin{bmatrix} \delta & a_1 & a_2 \\ a_1 & 1 & 0 \\ a_2 & 0 & 1 \end{bmatrix} \preceq 0 \text{ for } \omega \in [0,2\omega_p] \]  \hspace{1cm} (4)
where the notation $\Gamma(x, \omega) \geq 0$ denotes that matrix $\Gamma(x, \omega)$ is positive definite and $a_i$ for $i = 1, 2$ are known functions of $x$ and $\omega$ [8]. Using the well-known Lyapunov stability theory [9], it can be shown that $d_{k-1}(z)$ has all its zeros in the unit circle if and only if there exists a positive definite matrix $P_{k-1}$ such that

$$
\begin{bmatrix}
P^k_{k-1} & D_{k-1} \\
D_{k-1}^T & P_{k-1}
\end{bmatrix} > 0
$$

where $D_{k-1}$ is the canonical matrix obtained by using the coefficients of $d_{k-1}$ [8][9], and the notation $> 0$ denotes that the above matrix is positive definite. After the $(k-1)$th iteration is complete, one can solve the Lyapunov equation $P_{k-1} = D_{k-1}^T P_{k-1} D_{k-1} = I$ for the positive definite solution of $P_{k-1}$ and use it to construct the linear matrix inequality (LMI)

$$
Q_k(x) = \begin{bmatrix} P_{k-1} - \tau I & D \\ D^T & P_{k-1} - \tau I \end{bmatrix} \geq 0
$$

in the $k$th iteration to assure the stability of the IIR filter. In the above equation, a parameter $\tau > 0$ is introduced to control the stability margin of the filter. The $k$th iteration of the design can now be formulated as the SDP problem

$$
\begin{align}
\text{minimize} & \quad c^T x \\
\text{subject to:} & \quad \begin{bmatrix} \Gamma(x) & 0 \\ 0 & Q_k(x) \end{bmatrix} \succeq 0
\end{align}
$$

where $c = [1 \ldots 0]^T$ and $
\begin{bmatrix} \Gamma(x) & 0 \\ 0 & Q_k(x) \end{bmatrix}
$

is the $k$th iteration of the design of the analysis highpass filter $H_1$, and $x$ is a set of frequency points in the interval $[0, \omega_p]$. The optimization problem in (5) can be efficiently solved using the LMI toolbox of MATLAB. With $\beta(z)$ known, the analysis lowpass filter $H_0$ can be obtained.

### 2.2. Highpass Analysis Filter

Now let us examine the design of the analysis highpass filter $H_1$. If function $\alpha(z)$ is assumed to be the transfer function of a linear-phase FIR filter of even length of the form $a(z)$, we can define the error function for the analysis highpass filter $H_1$ as

$$
E_1(\omega) = H_1(e^{j\omega}) - H_{id}(\omega) = -\alpha(e^{j2\omega})H_0(e^{j\omega}) + e^{-j(2M+1)\omega} - H_{id}(\omega)
$$

where $H_{id}(\omega)$ is the desired frequency response of $H_1$, and $\alpha(e^{j\omega})$ is equal to $e^{-j(2M+1)\omega}$ for $\omega \in [\omega_s, \pi]$ and zero elsewhere. Now let $H_0(e^{j\omega}) = A(\omega)e^{-j2N_0\omega}$, where $A(\omega)$ is approximately equal to one in magnitude for $\omega \in [0, \omega_s]$, and let the frequency response of the FIR filter be $\alpha(e^{j\omega}) = e^{-j\omega(N_0-1)/2}\cos(\omega/2)P_\omega(\cos \omega)$, where $P_\omega(\cos \omega)$ is a Chebyshev polynomial of order $N_0/2 - 1$ that contains the coefficients of $\alpha(z)$. The error function in (6) can then be expressed as

$$
E_1(\omega) = e^{-j(2M+1)\omega}[1 - \cos(\omega)P_\omega(\cos(2\omega))]A(\omega)
$$

By setting $\partial E_1(\omega)^2 / \partial P_\omega$ to zero, we obtain the Chebyshev polynomial $P_\omega(\cos(2\omega))$ that minimizes $E_1(\omega)^2$ as

$$
P_\omega(\cos(2\omega)) = \frac{\Re[A(\omega)]}{|A(\omega)|^2 \cos \omega} \quad \text{for} \quad \omega \neq \pi/2
$$

Hence the design problem at hand can be formulated as the least $\rho$th minimization problem [10]

$$
\begin{align}
\text{minimize} & \quad \int_{I_p} W_n(x)[P_n(x) - P_q(x)]^T dx \\
\text{subject to:} & \quad \begin{bmatrix} \Gamma(x) & 0 \\ 0 & Q_k(x) \end{bmatrix} \succeq 0
\end{align}
$$

where $x = \cos(2\omega)$, $x_p = \cos(2\omega_p)$, $I_p$ is the interval defined by $I_p = (-1, -x_p)$ or $(x_p, 1)$, and $W_n(\omega)$ is a weighting function given by $W_n(x) = \cos(0.5\arccos x)A(0.5\arccos x)^2$. The optimization problem in (8) with $P = \infty$ can be solved using the Remes exchange algorithm [11]. With $\alpha(z)$ known, the analysis highpass filter $H_1$ can be obtained.

### 2.3. Selection of Design Parameters

We now describe some simple guidelines for the selection of parameters $N$, $n$, $M$, and $N_0$ for given design specifications. If filter $H_0$ were a linear-phase half-band FIR filter, its length could be predicted by using a formula due to Herrmann et al. [11] as

$$
L = \left[ \frac{D - FB^2}{B} + 1.5 \right]
$$

where $B = \frac{\omega_m - \omega_s}{2\pi}$, $F = 11.012$, $D = [0.005309(\log \delta_{so})^2 + 0.07114 \log \delta_{so} - 0.4761] \log \delta_{so} + [0.002666(\log \delta_{so})^2 + 0.5941(\log \delta_{so}) + 0.4278]$

In the above formulas, $\delta_{so}$ is the stopband ripple, $\omega_s$ and $\omega_p$ are the passband and stopband edges of the analysis lowpass filter, respectively; $[Q]$ denotes the largest integer smaller than $Q$. Now if $H_0$ is an IIR filter, then extensive simulations have shown that parameter $N$ could be taken to be one eighth of $L$ [10], i.e.,

$$
N = \left[ \frac{L}{8} \right]
$$

3. A CASE STUDY

#### 3.1. Design of a Filter Bank with Continuous Coefficients

We have applied the design method proposed in Section 2 to design an FIR filter bank with the following specifications: $\delta_{so} = 1.778 - 3$, $\omega_p = 0.45\pi$, and $\omega_s = 0.55\pi$. The length of a linear-phase half-band FIR filter was predicted to be $L = 60$; therefore, parameter $N$ for the low-delay IIR filter bank was chosen as $N = \left[ \frac{L}{8} \right] = 8$; with $N$ known, the other parameters can be deduced as follows: $n = 10$, $M = 23$, and $N_0 = 32$. We first design an FIR nonlinear-phase transfer function of order 35, represented by $\beta(z)$, by using the method proposed in [7]. A balanced approximation method [13] was applied to the FIR transfer function $\beta(z)$ to yield a stable rational function $\beta_0(z)$ of order 10. This $\beta_0(z)$ was then used as the initial guess in the SDP optimization described in Section 2. The SDP algorithm took...
one iteration to converge and the result was a stable rational function \( \beta(z) \) that gave an IIR filter \( H_0 \) with equiripple magnitude response. Next, the Remez exchange algorithm was applied to obtain a linear-phase FIR transfer function \( a(z) \) of order 31. The transfer functions \( H_0(z), H_1(z), G_0(z), \) and \( G_1(z) \) were then constructed using (1). The system delay of the filter bank was \( 2M + 2N + 1 = 63 \) s. The performance of the filter bank designed was evaluated and compared with that of the designs obtained with several existing methods. These include the methods in [4][7] where the same filter bank formulation was applied but with different selections of \( \beta(z) \) and \( a(z) \). Based on the method proposed in [4], we obtained an allpass transfer function \( \beta(z) \) of order 8 and a linear-phase FIR transfer function \( a(z) \) of order 31. By using the method proposed in [7], we obtained a nonlinear-phase FIR transfer function \( \beta(z) \) of order 35 and a linear-phase FIR transfer function \( a(z) \) of order 31. The linear-phase FIR filter bank with 32 lattice stages proposed in [14] was also considered in our comparison study. All the designs have the same system delay of 63 s.

The frequency responses of \( a(z), \beta(z), \) and analysis IIR filters \( H_0 \) and \( H_1 \) are shown in Figs. 2(a)-(c). The performance of the designs is illustrated in Table I, where \( \Delta \omega = \omega_p - \omega_s \) is the width of transition band for both \( H_0 \) and \( H_1 \), and \( \delta_{stop} \) are the stopband attenuations of filters \( H_0 \) and \( H_1 \), respectively. It is observed that the IIR filter bank designed by the proposed method outperforms the other methods in that it yields a narrower transition width and improved stopband attenuation. With regard to the implementation complexity, the allpass function of order 8 is implemented with 8 multipliers and 24 adders [2], the IIR function \( \beta(z) \) is realized in terms of a 10-stage lattice and ladder structure [11], and the linear-phase FIR \( a(z) \) is implemented using the direct form [12]. It is noted that the proposed method requires less multiplications and additions (at the original sampling rate) compared to the method in [7] but is not as economical as the methods in [4] and [14].

3.2. Multiplierless Implementation of the Filter Bank

It is advantageous to implement a filter bank without multiplications. A commonly used approach is to employ individual filters with coefficients that can be expressed as sums of a small number of power-of-two terms. In this way the filters can be implemented in terms of additions of shifted versions of the input. In what follows, we call such filter banks as filter banks with sum-of-power-of-two (SP2) coefficients. Optimal implementation of filter banks with SP2 coefficients can be achieved by using techniques such as simulated annealing or genetic algorithms but these methods require a large amount of computation. The approach we take here can be described as follows. First we design a filter bank with continuous coefficients. Next we assign a certain number of bits for each coefficient based on its magnitude, and determine its lower and upper SP2 bounds. For the filter bank designed in Section 3.1 there were 21 coefficients in \( \beta(z) \), five of which were very small in magnitude and were not sensitive to quantization; these were fixed to their nearest SP2 values. Then through an exhaustive search we selected either the upper bound or the lower bound for each of the 16 remaining coefficients such that the objective function

\[
E_k(H_k) = \max_k \| H_k(\omega) - H_k(\omega) \|, \quad k = 0, 1, \omega \in [0, 2\pi]
\]

is minimized. In (11) \( H_k(\omega) \) for \( k = 0, 1 \) are the frequency responses with the coefficients quantized and \( H_k(\omega) \) for \( k = 0, 1 \) are the corresponding desired frequency responses. For the linear-phase FIR transfer function \( a(z) \), there were 16 coefficients that needed to be quantized to their SP2 values, and the exhaustive search was also performed as for transfer function \( \beta(z) \). The search for the optimal SP2 coefficients for \( \beta(z) \) and \( a(z) \), which involved the selection of the optimal combination out of \( 2^{16} \) combinations in each case, was carried out on a Pentium II 400 MHz PC. The resulting magnitude responses of the multiplierless 2-channel IIR filter bank are depicted in Fig. 2(d). The average number of power-of-two terms used was 2.9. It is observed that the filter bank with SP2 coefficients still offers more than 50 dB stopband attenuation.
