Novel Design of Neural Networks for Handwritten Chinese Character Recognition

Devil H.F. YIP and William W.H. YU
Department of Industrial and Manufacturing Systems Engineering
The University of Hong Kong
Pokfulam Road, Hong Kong

ABSTRACT

Handwritten Chinese character recognition systems invariably use different image processing techniques to preprocess the input image before the main classification and recognition techniques are used. The authors proposed a different approach to the system philosophy of solving the handwritten Chinese character recognition problem for no preprocessing is necessary. The Chinese characters are treated as ideographs. The proposed system comprises of a Rough Classifier which control the different Fine Classifiers. Each classifier is an optimized artificial neural network using genetic algorithms. A reduced system has been implemented. The result shows that the proposed system has higher recognition rate than the similar systems reported and is more efficiency.

Keywords: Handwritten Chinese Character Recognition, Neural Networks, ETL9B

1. INTRODUCTION

Learning Chinese characters are much more difficult than learning the characters of the western languages. The reason is that the Chinese character set is very large. Many of Chinese characters have the same radical but vary in number of strokes. A Chinese character can comprise of up to forty-eight strokes. Learning the Chinese characters is a formidable task for a person. It is even more so to develop a computer Chinese character recognition (CCR) system. To add to the difficulty of such a task is that the Chinese characters are written in a number of different styles. Automatic recognition of the printed Chinese characters is comparatively a lot easier than handwritten Chinese characters. An automatic CCR system which is fast and has a high success rate will greatly simply and accelerate converting a handwritten Chinese document into a printed document.

The CCR has been the subject of intensive research for over three decades. In 1966, Casey and Nagy [1] at IBM reported one of the first attempts at CCR for a set of about 1,000 printed Chinese characters. Since then, a large number of papers and reports have been published on this topic. Both handwritten and printed English character recognition systems, off-line and on-line printed CCR systems, and on-line handwritten CCR systems for commercial used have been well developed. There are still on going on off-line handwritten CCR systems.

Character recognition techniques fall roughly into three categories. The first category employs global transformation and series expansion. Examples are Fourier transform [2], Hadamard and Harr transform [3], Walsh transform [4], Hough transform and code transform [5]. These transformations are generally easy to implement but computationally demanding. The second category compares features obtained from the spatial distribution of pixels. Some examples are cross counts, loci features [6] and moments [7]. These methods are fast but difficult to implement. Third category matches the geometrical or topological features such as strokes and bays in various directions, end points and loops [8]. These techniques are powerful but complex in their implementations requiring long processing time. Much of the processing time is spent on extractions of the geometrical or topological features of the character.
Some researchers have also used artificial neural networks (ANNs) for character recognition [9-11]. However, most of the tests are carried out in small scales only. These approaches generally do not have very high recognition rate when applies to handwritten Chinese characters.

The challenge is to develop an effective handwritten Chinese character recognition (HCCR) system to accurately recognize about 50,000 Chinese characters. A reasonable commercial system should be able to recognize at least 5,000 characters in common use. Some high recognition rate HCCR systems have been reported [12-16]. ANNs are used as the rare end of the systems for the recognition of Chinese characters. The front end of the systems comprises of some preprocessing commonly found in computer vision systems. The results of the preprocessing stages are quantified and fed to the input nodes of the ANN. Senda et al., [12] used a pattern recognition method, minimum distance classifier, to calculate the eigenvectors of the prototypes. Kato and Nemoto [13] use smoothing, noise reduction and normalization in their preprocessing stage. Guo et al., [14] include non-linear normalization, 3 x 3 mask smoothing and extraction of the contour in the preprocessing stage. Saruta et al., developed the HCCR systems, ELNET [15] and ELNET-II [16], where input data first undergo non-linear normalization and outline extraction prior to the training of ANN. The preprocessing of data may corrupt information vital for differentiating between two Chinese characters with similar strokes and thus render the recognition network less effective. In addition, time must be spent to process every character presented to the system before the feature extraction process.

In this research, the authors propose a new approach to HCCR using ANN. The approach differs significantly from the investigations taken up by the other researchers. The preprocessing stage used by the others will not be used in the proposed system. The topology of the ANN is optimized using genetic algorithms (GAs) to determine the optimal parameters and the topology of the adaptive back-propagation network for similar Chinese character recognition under the specified conditions. The performance of the proposed approach is analyzed using the ETL9B database provided by the Electro-Technical Laboratory from Japan. The same database is used in the work of Saruta et al. Section 2 presents the system philosophy of the proposed HCCR system. Section 3 describes network architecture and the training algorithm. Section 4 presents the training and test results of the proposed system. In section 5, conclusions and future works are given.

2. SYSTEM PHILOSOPHY

An ANN mimics the ability of a person to recognize complex patterns without having to perform complex analysis of the pattern. A child learning to recognize complex patterns such as Chinese characters generally do not rely on any high level analytical skills. A child has this ability before acquiring any formal lessons or schooling. The authors argue that using image processing technique at the front end of a HCCR system somewhat prevents the ANN to mimic a person’s full ability to recognize complex patterns. When a child goes to school, the analytical skills are very important. However, to implement a person’s analytical skills in a HCCR system means enormous efforts in deriving complex equations, algorithms and other sophisticated and time consuming techniques. The results may not always be encouraging in proportion to the efforts made.

The proposed system mimics how child learns Chinese characters and does not use the above preprocessing techniques. The system treats the Chinese characters as ideographs. The authors also argue that when a child learns the characters, he or she somewhat classifies the characters into the simpler and the more complex categories without invoking any critical and analytical procedures. This primitive mental classification process facilitates an efficient recognition process. The mental search for matches can be directed towards the simpler or the more complex set of characters as the case may be. Thus the system philosophy comprises of the following components.

1. A person has the ability to learn and recognize a large set of patterns such as Chinese characters without using more complex analytical skills.
2. A person tends to classify the patterns into simple and complex categories of various degrees. The boundary between any two categories varies from person to person and is not analytically derived.

3. A person tends to classify a large set of Chinese characters according to various degrees of similarities in terms of general outlines, shapes, portions of the characters, or radicals. Again these classifications need not be the result of some critical examinations of the characters. The results from such classification exercises may differ tremendously with the results produced by a learned individual.

This paper investigates the proposed philosophy using a reduced system. The reduced system assigned a limited function to the Rough Classifier. It classifies the data set in terms of their general shapes. The characters to be classified are those having the character “□” as the outer frame of the characters. Examples of these set of characters are: \{ 土, 田, 井, 工 \}.

Figure 1 illustrates the conceptual architecture of the ANN HCCR system based on the system philosophy above.
3. NETWORK ARCHITECTURE AND TRAINING ALGORITHM

To implement and test a substructure of the proposed ANN HCCR system, the test system comprises of a Rough Classifier and a number of Fine Classifiers. The input data are the pixel binary output of the character presented to the input nodes of all the classifier networks simultaneously. Each of these classifiers is a stand-alone ANN and comprises of input nodes, hidden layers and output nodes. In addition to the input data the Fine Classifiers input nodes also receive signals from the Rough Classifier. The Rough Classifier first groups the similar characters into the same class according to their pixel density distribution.

The output data of the Rough Classifier represent complexity of strokes, the lexicographical radicals, the spatial distribution of strokes and the overall shape of the character. The weighted output from the Rough Classifier to the Fine Classifiers trigger or inhibit the Fine Classifiers responses to the input data. Then, the triggered Fine Classifier categorizes the character and the output will produce the relevant Chinese character code specified by the system (such as Big 5) through an appropriate converter. Each Fine Classifier learns and recognizes a subset of the character set. The workloads of the Fine Classifiers are thus divided (not necessarily evenly) amongst them. This approach greatly improves the efficiency of the system.

One of the critical problems with using ANNs is in designing the network topology for a given problem such as character recognition. Typically the network topology (number of hidden units, number of hidden layers and the interconnects) and the parameters in the network (learning rate, momentum, weight decay, initial weight, etc.,) are determined through trials and experiments which could often be long and tedious in design considerations. The temptation is to accept any solutions which may not be optimal. In some situations, the problem may appear insolvable after a long process of trials and experiments for the right combination of parameters has not been selected.

The authors have shown that genetic algorithms (GA) are suitable tools for determining the optimal topology and parameters of ANN [17-18]. GAs have the advantage of being less likely to get stuck in a local optima. When there is no a priori knowledge about the parameter space and the search space is large, the optimization process may take a long time to converge.

The back-propagation network has been adopted because it is capable of approximating arbitrary mapping given a set of examples and adaptive back-propagation (ABP) technique [19] is used to achieve fast convergence during the training process. Since the authors are using the ABP for training, the ANNs are restricted to a feed-forward multi-layer perception (MLP). The MLP may be randomly or fully connected. In fully connected MLP, every node in a layer is connected only to all the nodes in a subsequent layer.

GAs have been used to determine the most effective number of hidden layers, number of hidden nodes per layer and interconnects. For each jth genetic string or chromosome, the training of the network produces a fitness value given by:

\[ f_j = \frac{1}{\sum W_i F_i(X_{ij})} \]

Where \( W_i \) is the significance of weighting factor for the \( i \)th parameter, \( F_i \) is a function for the \( i \)th parameter and, \( X_{ij} \) is the \( i \)th parameter value.

The parameters of the fitness values included are: the overall error, the maximum number of nodes in the network, the number of links in the network, the number of epochs required to train the network, maximum number of epochs specified, the number of misclassified patterns during training/recall, the number of nodes out of the tolerance limit during training/recall, and the total number of training/recall patterns. Each gene represents a specific network topology and the fitness value indicates its performance.
Crossover and mutation follows each training process and the genes compete for survival based on their fitness values. The optimization process is subject to some specified conditions. The network of the system has a maximum of 2 hidden layers each with a maximum of 30 hidden nodes; 50 generations with population size 50; uniform crossover probability 0.6 and mutation probability 0.01 (based on the recommendation of DeJong [20]).

4. TRAINING AND TEST RESULTS

The training and testing of this two-stage classifier were conducted on a Pentium based personal computer. The character database ETL9B, which was prepared by Electro-Technical Laboratory from Japan, contains 3036 categories (2965 handwritten Chinese characters and 71 handwritten Japanese characters) in 200 difference patterns per character. In principle, in larger the training set is, the more robust the network. The authors used the same training and testing conditions of the experiment done by ELNET [15] and ELNET-II [16], and cross validation in the experiment. The data available are in set of 200 characters. The experiment used 36 sets of characters. All the characters are “□” as the outer frame. Each character set comprises of 200 samples and 180 samples per character set were used for cross validation. The input data were 64 x 63 binary patterns. Each was subdivided into 8 x 8 square matrices. Each square matrix was a 10 x 10 pixels array overlapping its neighing square by 2 pixels width.

Table 1 Recognition results of the proposed system with 180 sets data in training

The average recognition rate of the proposed system is 99.05% with a fully connected optimal topology of 64 input nodes, 18 hidden nodes in the first hidden layer, 14 hidden nodes in the second hidden layer and 16 binary output under the specified conditions. The result is better than the ELNET (94.54%) and ELNET-II (95.84%) with the same character database. The authors have also conducted an experiment using only 100 samples per character set for training and 100 for tests. The average recognition rate is 98.71% which compares well against ELNET and ELNET-II which used a larger training sample set of 180.

5. CONCLUSIONS AND FUTURE WORKS

Though the experiments were conducted on a reduced system, the result shows that the proposed system philosophy is implementable, effective and of high performance. The authors in another paper have reported the results of recognition of another group of characters on the same reduced system. All the results show that the full-scale systems can be implemented and equally successful results can be expected. The implementation of the full-scale systems is currently underway.
