ABSTRACT

We present the results of a high-resolution ($\theta_{\text{FWHM}} \sim 0.5''$) 12 ks Chandra HRC-I observation of the starburst galaxy IC 342 taken on 2006 April 2. We identify 23 X-ray sources within the central $30' \times 30'$ region of IC 342 and resolve the historical ultraluminous X-ray source (ULX), X3, near the nucleus into two sources, namely, C12 and C13. The brighter source C12, with $L_{0.08-10\,\text{keV}} = (6.66 \pm 0.45) \times 10^{38}\,\text{erg s}^{-1}$, is spatially extended ($\sim 82\,\text{pc} \times 127\,\text{pc}$). From the astrometric registration of the X-ray image, C12 is at R.A. = 03h46m48.43s, decl. = +68°55'47.45", and is closer to the nucleus than C13. Thus, we conclude that source is not an ULX and must instead be associated with the nucleus. The fainter source C13, with $L_{0.08-10\,\text{keV}} = (5.1 \pm 1.4) \times 10^{37}\,\text{erg s}^{-1}$, is consistent with a point source located at 6.51" (position angle P.A. $\approx 240'$) of C12. We also analyzed astrometrically corrected optical Hubble Space Telescope (HST) and radio Very Large Array images; a comparison with the X-ray image showed similarities in their morphologies. Regions of star formation within the central region of IC 342 are clearly visible in the HST Hα image, which contains three optical star clusters and our detected X-ray source C12. We find that the observed X-ray luminosity of C12 is very close to the predicted X-ray emission from a starburst, suggesting that the nuclear X-ray emission of IC 342 is dominated by a starburst. Furthermore, we discuss the possibility of active galactic nucleus (AGN) emission in the nucleus of IC 342, which we can neither prove nor discard with our data.

Subject headings: galaxies: individual (IC 342) — galaxies: starburst — X-rays: galaxies

1. INTRODUCTION

IC 342 is a nearby (1.8 Mpc; see Buta & McCall 1999 for a review), almost face-on ($i = 25° \pm 3°$; Newton 1980) late-type Sc/Sd galaxy in the Maffei Group, which is one of the closest groups to our Galaxy, with well-developed spiral arms. Infrared and radio observations indicated moderately strong nuclear starburst activities (Becklin et al. 1980; Rickard & Harvey 1984) in IC 342, whereas X-ray observations with Einstein (Fabbiano & Trinchieri 1987), ROSAT (Bregman et al. 1993), and ASCA (Okada et al. 1998; Kubota et al. 2001) indicated that the majority of the X-ray emission came from a few ultraluminous X-ray sources (ULXs). ULXs are defined as off-nuclear X-ray sources whose luminosities are greater than $2.8 \times 10^{39}\,\text{erg s}^{-1}$, the Eddington luminosity of a $20\,M_\odot$ black hole. One of the ULXs identified, X3 (based on the designations from Fabbiano & Trinchieri 1987), was located near the galactic center and was reported to be coincident with the center of IC 342 at the resolutions of the ASCA (FWHM $> 1''$) and ROSAT (FWHM $\approx 5''$) data.

Optical and near-infrared observations of the inner region of IC 342 revealed the presence of a nuclear star cluster (Böker et al. 1999). Photometrically distinct, luminous, and compact stellar clusters were often found in the centers of late-type spiral galaxies, such as NGC 6240 (Lira et al. 2002) and NGC 1808 (Jiménez-Bailón et al. 2005). Schnurrer et al. (2003) studied high spatial resolution (FWHM $\approx 1.2''$) millimeter interferometric observations of the $^{12}\text{CO}(2-1)$ emission of IC 342 and concluded that gaseous matter was accumulating at the nucleus through streaming motions. This suggested that star cluster formation could be a repetitive process, and this process could have provided the fuel for starburst activities. As a result, if X3 were indeed associated with the galactic center, its emission may not have been from a single ULX, but could have been associated with the nuclear star cluster. However, the early identification of X3 as an ULX was uncertain due to the limited resolution of the early X-ray data.

The higher light collecting power and lower background level of XMM-Newton provided a clearer picture of the nuclear X-ray source X3. A 10 ks observation of IC 342 was taken with the PN CCD camera and two MOS CCD cameras using the medium filter on 2001 February 11. Two independent studies by Kong (2003, hereafter K03) and Bauer et al. (2003, hereafter B03) on the data set yielded similar results, with a total of about 35 sources detected. The slope of the X-ray luminosity function was determined to be $\sim 0.5$, which was consistent with other starburst galaxies and Galactic high-mass X-ray binaries (HMXBs). However, there were differences in the two studies about the nature and properties of the nuclear source. K03 found that the nuclear X-ray source was consistent with the instrumental point-spread function (PSF) of a point source located $\sim 3''$ from the galactic center, suggesting an off-center scenario. K03 fit the nuclear source with a power law + blackbody spectral model ($kT = 0.11\,\text{keV}$, $N_{\text{H}} = 8.7 \times 10^{21}\,\text{cm}^{-2}$, photon index $\alpha = 2$) and found the disk temperature was about 5–10 times lower than expected. Such a cool disk system might be evidence of intermediate mass black holes (IMBHs; Miller et al., 2003, 2004). However, we could not ignore the scenario of a stellar mass black hole with inner disk outflows during high accretion rate period (King & Pounds 2003), and that of a magnetic corona atop a cool accretion disk in which X-rays were reprocessed to give soft photons (Beloborodov 1999; Miller et al. 2006). The black hole mass of the nuclear X-ray source was estimated to be between 220 and 15,000 $M_\odot$ (K03). Together with the unphysical spectral fit with the broken power-law model, K03 ruled out the
The possibility of an accreting stellar mass black hole with beamed relativistic jet emission. On the other hand, B03 suggested that the nuclear source was extended, mainly in the soft band, and its emission could fit by a model of a point source plus a uniform disk with a radius of $\approx 8''$, which was consistent with a supernova-heated hot gas. Moreover, the nuclear source spectrum was fit by B03 with a MEKAL + power law model ($kT = 0.3 \text{ keV}, \alpha = 2.52$, $Z = 6.39 Z_\odot, N_{\text{HI}} = 6.8 \times 10^{21} \text{ cm}^{-2}$), including contribution from the Fe L-shell emission complexes at $0.5 \text{ keV}$, $1.0 \text{ keV}$. They found that a large fraction of the X-ray emission was likely to be thermal in origin. The relative contribution of the MEKAL component to the total absorbed flux was about 45% and 1% in the $0.5-2$ and $2-10 \text{ keV}$ band, respectively, leading B03 to suggest that the hard component might be due to a number of circum-nuclear X-ray binaries.

The limited astrometric accuracy and spatial resolution of the previous X-ray observations restricted our ability to determine the exact nature of the X-ray properties at the center of IC 342. In this paper, we report a new high-resolution (FWHM $\approx 0.5''$) Chandra X-Ray Observatory observation of the starburst galaxy IC 342. The observation and the data reduction procedures of the X-ray data, and the associated optical data for comparison, are presented in $\S$ 2. In $\S$ 3, the analysis of the data, including source detection, photometry, and astrometric registration of the X-ray sources, is described. In $\S$ 4, we present the results of the associated counterparts of the nuclear X-ray sources in optical and radio images and the properties of the nuclear sources. We discuss the nature of nuclear X-ray emission of IC 342 in $\S$ 5, and we present a summary of our findings in $\S$ 6.

2. OBSERVATIONS AND DATA REDUCTION

2.1. X-Ray

IC 342 was observed on 2006 April 2 starting at 15:15:44 (UT) with the Chandra High-Resolution Camera (HRC-I) for a total exposure time of 12.16 ks, with a photon energy range of $0.08-10 \text{ keV}$. The nominal pointing of the instrument was near the center of the galaxy and the total region covered by the observation was $30' \times 30'$, which covered most of structure of the galaxy, including the spiral arms. The field of view of the Chandra observation is presented in Figure 1 (left), overlaid with the Digitized Sky Survey (DSS) image of IC 342. The central $5' \times 5'$ of IC 342 is magnified in Figure 1 (right) for reference. The X-ray data were analyzed with the Chandra Interactive Analysis of Observations software package (CIAO) version 3.3 and Chandra Calibration Database (CALDB) version 3.2.1 software applied on the level-2 event fits file. The Chandra data had gone through Standard Data Processing\(^1\) (SDP, or the pipeline) with updated calibration procedures, including instrumental corrections and filtering of good time intervals, applied.

There were four other archival Chandra IC 342 data sets: three Advanced CCD Imaging Spectrometer (ACIS-S) observations (each 10 ks) in subarray mode centered on one of the ULXs (X1), and one 3 ks HRC-I observation. For the three ACIS-S data sets, the detectors did not cover the nuclear region of IC 342 as the subarray mode was used to reduce pileup. The 3 ks HRC-I observation, on the other hand, had insufficient signal for source detection at the galactic center. Therefore, only the 12 ks HRC-I image was analyzed in this work.

IC 342 was also observed four times between 2001 and 2005 with XMM-Newton. Of these four observations, the data taken in 2001 were studied by B03 and K03. We have retrieved the 2001 EPIC data for the analysis of the X-ray spectrum of the nuclear sources. The event files were reprocessed and filtered with the XMM-Newton Science Analysis Software (SAS, ver. 7.1.0), and we used the HEAsoft version 6.2 and XSPEC version 12.3.1 packages to perform spectral analysis.

2.2. Optical

We also analyzed archival Hubble Space Telescope (HST) broadband and emission-line images of IC 342 for comparisons with the X-ray data. We searched the HST Data Archive for images with pointings that included the central part of the galaxy. The calibrated and data-quality images were retrieved, with preliminary CCD processing, including bias and dark subtraction, flat-fielding, and shutter-shading correction, automatically applied using calibration frames closest to the time of the observations. The fields were inspected to ensure that the galactic nucleus did not fall on the boundaries on any of the CCD chips. We found that most of

\(^{1}\) See http://cxc.harvard.edu/ciao/dictionary/sdp.html.
the archival images were saturated at the central region of the galaxy. The only unsaturated images were the Wide Field Planetary Camera 2 (WFPC2) images taken on 1996 January 7 in broadband $V$ ($F555W$) and $I$ ($F814W$), and in narrowband H$\alpha$ ($F656N$), and they were selected for comparison with our Chandra HRC-I data. The exposure time of each frame was 260 s each for the $V$ and $B$ bands and 500 s for H$\alpha$. Mosaics were produced using the STSDAS task mosaicc, which removed known relative rotations and geometric distortions of the individual WFPC2 chips. Astrometry of the calibrated HST images was corrected using the coordinates from the USNO-B1.0 Catalog (Monet et al. 2003) for comparison with the positions of X-ray sources in the same reference frame. Details of the astrometric registration of the data will be described in §3.3.

3. ANALYSIS

3.1. X-Ray Source Detection

We performed source detection on the X-ray image using the wavdetect algorithm (Freeman et al. 2002), which employs a wavelet method to detect point sources. This detection threshold correlates to less than one false detection in the Chandra HRC-I field due to statistical fluctuations in the background (Freeman et al. 2002).

The run time of wavdetect depends heavily on the selected resolution of the image, and a resolution of 1024 × 1024 was considered to be the practical size limit for the input data on most desktop computers. We tested running wavdetect on the central part of the image containing the galactic center with binning factors 1, 2, 4, 8, 16, and 32. An exposure map, created using CIAO, was applied for each binning to normalize the images and to correct for instrumental artifacts caused by imperfections of the Chandra mirror and detector, especially at the edges of the field. We found the list of sources detected depended on the binning factor applied. A binning factor of 4 was used in the final data reduction as a compromise between spatial resolution and faint source detection. The Chandra field was divided into four equal quadrants with overlapping at the central regions before being recombined to the full frame. The final image scale with a binning factor of 4 was 0.53′′ pixel$^{-1}$.

To generate the final source list, we applied two additional selection criteria for the sources identified by the wavdetect algorithm:

1. The source should be detected in at least two different binning images, with one of them being that with a binning factor of 4.
2. The signal-to-noise ratio (S/N) of the source had to be greater than 3 in the image with a binning factor of 4.

With these selection criteria we detected a total of 23 X-ray sources in our Chandra HRC-I image of IC 342. Properties of the detected sources are summarized in Table 1. A total of 14 and 8 of our
sources were also previously detected in the \textit{XMM-Newton} (B03; K03) and \textit{ROSAT} observations (Bregman et al. 1993), respectively. The alternate \textit{XMM-Newton} and \textit{ROSAT} source IDs are listed in Table 1. The locations of all sources detected are shown overlaid on the DSS image in Figure 1. A majority of the identified sources are located in the spiral arms of the galaxy, as previously noted by B03 and K03 with \textit{XMM-Newton} observations. Using the Chandra Deep Field data (Brandt et al. 2001), we estimated that there could be 9–10 background objects within our 30′ × 30′ Chandra frame, implying that ∼40% of the sources currently detected could be background objects.

With the high-resolution \textit{Chandra} HRC-I image, we were able to resolve for the first time X-ray emission from the center of IC 342 into two distinct components, namely, C12, the brighter and extended component near the center of the galaxy, and C13, a much fainter component located 6.51′′ from C12 at P.A. ≈ 240°. The two sources could be identified by the \textit{wavdetect} algorithm when the binning factor was set to either 2 or 4, suggesting that they were genuine detections. Images of the central 25′′ × 25′′ of the \textit{Chandra} HRC-I image of IC 342 are shown in Figure 2, together with the positions of the two nuclear sources C12 and C13 and the X-ray flux contours. Details of the X-ray emission morphology will be discussed in § 4.1.1.

### 3.2. Photometry

We extracted the integrated counts of the 23 detected X-ray sources of IC 342 using the CIAO tool \texttt{dmextract} and listed the results in Table 1. The source regions were defined in DS9 using circular apertures with different radii based on the relative brightness of the source compared to the local background and their off-axis angles. All the background regions were extracted using circular annuli centered on individual sources. The only exception was the nuclear source C12, in which an elliptical aperture was used because of its extended nature. Moreover, the background regions of the two nuclear sources C12 and C13 (6.51′′ apart) had to be modified to avoid overlapping. We used WebPIMMS to convert the count rates for all detected X-ray sources into unabsorbed 0.08–10 keV luminosity by assuming an absorbed power-law model with $N_H = 8 \times 10^{21}$ cm$^{-2}$ and $\alpha = 2$, adopted from the average parameters derived from spectral fitting of the \textit{XMM-Newton} data by K03. These results are also presented in Table 1. This set of average parameters was similar to that derived from the same \textit{XMM-Newton} data set by B03, with $N_H = 3.4 \times 10^{21}$ cm$^{-2}$ and $\alpha = 1.63$. The difference in 0.08–10 keV luminosities obtained with these two sets of spectral parameters is about 10%, with slightly lower values for the parameters from K03.

For C12, B03 and K03 derived the X-ray flux by fitting the source spectrum with a simple absorbed power-law model (B03; $N_H = 4.0 \times 10^{21}$ cm$^{-2}$ and $\alpha = 2.67$; K03; $N_H = 3.2 \times 10^{21}$ cm$^{-2}$ and $\alpha = 2.53$). For comparison, our adopted flux for C12 is smaller by about 40% than the B03 model and about 30% larger than the K03 simple power-law model by using the average of the X-ray sources’ parameters. In this paper, we adopt the value from K03, except for Table 1 in which we use the average parameters from K03 as described above.

There is a large uncertainty in the distance estimate to IC 342 due to the large uncertainty in the amount of dust extinction toward the Galactic center along that line of sight. Distance estimates of IC 342 range from 1.5 to 8 Mpc (Buta & McCall 1999). A distance of 1.8 Mpc was assumed in this paper (corresponding to a scale of 10″ = 87 pc), identical to that in Böker et al. (1997, 1999) and K03, and similar to that (2 Mpc) assumed by Meier & Turner (2005). Using an elliptical (4.6″ and 9.9″ for semimajor and semimajor axis, respectively) integrating window to include all the dif-
In order to identify optical counterparts of our Chandra X-ray sources in the HST data, we first registered their positions to the same reference frame for comparison. We used the USNO-B1.0 Catalog (Monet et al. 2003) to improve the astrometric accuracies for both the Chandra and HST images. The advantage of using this is that proper motions are already included in the catalog, and hence we can correct for them. The nominal rms accuracy of the USNO B1.0 catalog is 0.2\arcsec.

The astrometry of our Chandra image can be improved when one or more X-ray sources are associated with optical or radio sources of known positions. As seen in Figure 1, one of the brightest sources, C5, is clearly associated with a bright stellar object within 1\arcsec in the DSS image. This source was also previously identified to be associated with a star in the ROSAT observation (source 4 in Bregman et al. 1993) and in the XMM-Newton observation (X12 in K03). The spectrum of X12 is soft and can be fit with a blackbody model (kT = 0.17 keV). B03 determined the X-ray to optical flux ratio log (f_X/f_Opt) of X12 to be \( \leq -3 \), which was consistent with that expected from a foreground star of log (f_X/f_Opt) \( \leq -1 \). B03 and K03 also identified it to be a foreground star. Using the USNO-B1.0 Catalog, we found that the source C5 was offset by 0.42\arcsec (right ascension offset by 0.13\arcsec and declination offset by 0.40\arcsec) from this foreground star, which was within the expected 0.5\arcsec pointing accuracy of the Chandra data. While there are other X-ray sources which could be associated with point sources in the DSS image, their positional offsets are either \( \geq 0.5\arcsec \) or their S/Ns were too low (\( \leq 3 \)) to make firm registrations with their optical counterparts. Thus, we corrected the pointing of the Chandra image using the CIAO command wcsupdate by linearly shifting it until C5 and the star coincided. This astrometric reference was applied to all the sources, and their shifted positions were tabulated in Table 1.

The astrometry of the HST images was corrected using the IRAF task ccmap. With many bright stars within the WFPC2 frame, we could visually identify stars from the catalog in the HST data products and compare them with the USNO-B1.0 Catalog to improve the astrometry. A total of seven stars were used for astrometric registration for the V- and I-band data and three stars for the Hα data. The rms positional errors returned by ccmap were 0.30\arcsec for V, 0.32\arcsec for I, and 0.0021\arcsec for Hα. These registrations are similar to that of our Chandra HRC-I images, hence allowing meaningful spatial comparison of the sources in different wavelengths.

4. RESULTS

4.1. Morphology of the IC 342 Center

4.1.1. X-Ray

The high spatial resolution of the Chandra HRC-I image (\( \theta_{FWHM} \sim 0.45\arcsec \)) provides an unprecedented detailed look into the X-ray emitting structure of the IC 342 galaxy center. Detailed structures of the X-ray emission from the IC 342 center are illustrated in Figure 2 with the central 25" \( \times \) 25" of the Chandra image. The two nuclear sources, C12 and C13, are separated from other X-ray sources and stand out from the low diffuse X-ray background. The brighter source, C12, was observed to have at least two components. The first component is the core emission of radius \( \sim 2" \) at the center, roughly consistent with that bounded by the X-ray contour line of 1.4 counts. The second component is the diffuse emission out to a radius of 5", with an asymmetric extension along the north-south direction. The spatial extent, derived from the X-ray image at 99.5% linear scale, is 14.6" in the north-south and 9.4" in the east-west directions (127 pc \( \times \) 82 pc assuming a distance of 1.8 Mpc), resulting in a major-to-minor axis ratio of \( \sim 1.6 \). The observed north-south elongation is similar to that observed in the near-infrared wavelength by Böker et al. (1997), who detected a diffused emission with a major axis of 110 pc and a high surface brightness source at the center. The authors interpreted the results as evidence for a small-scale nuclear stellar bar and a central concentration of stars.

We determined the X-ray luminosity of the core and the circumnuclear diffuse regions of C12 by extracting, respectively, the source counts of the inner 4" region with a circular aperture, and the source counts of an annulus of \( r = 2" - 5" \). The resulting X-ray luminosities (assuming the same spectral and distance parameters as listed in § 3.2) are \( L_X^{core} = 3.14 \times 10^{38} \text{ erg s}^{-1} \) and \( L_X^{diffuse} = 3.34 \times 10^{38} \text{ erg s}^{-1} \), implying roughly equal flux contributions in X-rays from these two regions.

To analyze the structure of emission from C12, its radial flux profile was extracted and normalized at the center. The results are shown in Figure 3 (top left). As a comparison, the normalized radial flux profile of the Chandra PSF at the location of C12 derived from the Chandra PSF simulator, the Chandra Ray Tracer (ChaRT),\(^2\) is also shown (dashed line). The emission from the core component of C12 at the central \( r < 2" \) is consistent with that from a point source. However, the diffused emission component at radius \( r \geq 2" \) does not decrease as steeply as that of the PSF. We also computed the radial flux profile of a point source plus a uniform \( r = 5" \) circular disk at the location of C12 computed from the simulation task MARX.\(^3\) The results (dot-dashed line), also shown in Figure 3 (top left), are generally consistent with that observed for C12, with a hint of slowly decreasing surface brightness in the range \( r \sim 2" - 5" \) for C12. A Kolmogorov-Smirnov test (K-S test) was performed to measure the difference between the radial profile of C12 and the models. The K-S test statistic \( D \), the maximum vertical deviation between the two curves, is 0.78 (confidence probability < 0.01%) for C12 and a point source, and 0.33 (confidence probability = 6.0%) for C12 and a point source plus a 5" disk. The surface brightness profiles for selected bright X-ray sources, C3, C6, and C21, are also plotted in Figure 3 (top right, bottom left, and bottom right, respectively) for comparison. The K-S statistic \( D \) of the reference sources C3, C6, and C21 are in a much lower range of 0.17–0.33 (corresponding to confidence probabilities of 2.2%–76.0%). These results reinforce the conclusion that the emission from C12 is not consistent with that from a point source; the X-ray emission of C12 might be due to multiple sources, diffuse emission, or a combination of both. However, we cannot conclude whether the emission is consistent with the various components proposed by Böker et al. (1997) due to the limited resolution of the X-ray data.

The newly detected X-ray source C13 is one of the faintest sources in our Chandra observation, with \( L_{C12}/L_{C12} \approx 6\% \). We failed to extract the radial profile of C13 and cannot determine whether it is a point source or a diffused source because of insufficient count statistics. We also could not exclude the possibility that the emission was actually part of the nebulosity of the extended emission component of C12.

4.1.2. Comparison of X-Ray with Optical Data

We compared the Chandra image of the galaxy center of IC 342 with the optical observations. The registered positions of the X-ray nuclear sources C12 and C13 are overlaid on the HST V-band and Hα images of the central 17" \( \times \) 17" region of the IC 342 in Figures 4 (top) and 5 (top), respectively. The spatial extent of the C12 core emission is also shown by a 4" circle (blue dashed circle) in the figures. The HST I-band image was also

\(^2\) See http://cxc.harvard.edu/chart/.
\(^3\) See http://space.mit.edu/ASC/MARX/.
analyzed but was found to be similar to the $V$-band data and thus is not shown. In the HST images, there are many star-forming regions at the center of IC 342 with obscured emissions and bright knots. Both HST images show that the optical emission from the central $d \approx 5''$ of IC 342 is concentrated in three star clusters aligned in the north-south direction. The star clusters have also been observed previously in the near-IR CO band by Böker et al. (1999). We refer to the three clusters here as the nuclear star cluster (NSC; middle), SC1 (top), and SC2 (bottom). The centroid of C12 lies close to that of the optical maximum of the NSC, with an offset of 0.53" measured in all the $V$, $I$, and H$\alpha$ images. The observed separations were only slightly larger than the uncertainty of the X-ray boresight correction of C12 (0.45") in our Chandra image.

Using the near-IR CO band observations, Böker et al. (1999) deduced that the NSC is a relatively young cluster with an age of $10^{6.8}$–$10^{7.8}$ yr and a mass of $M_{\text{NSC}} \approx 6 \times 10^6 M_\odot$. These results favored an instantaneous burst model rather than a constant star formation rate model for the NSC, meaning the dominant stellar population is of the same age as the NSC. In addition, the NSC could have formed as a result of gas flowing to the nucleus initiated by torques from a nuclear stellar bar. The H$\alpha$ image is consistent with this scenario in that it shows gas spiraling around the NSC (see Figs. 4 and 5).

The X-ray contours are overlaid on the broadband $V$ and H$\alpha$ images of IC 342 in Figures 4 (bottom) and 5 (bottom), respectively, for a comparison of the diffuse X-ray emission with the detailed structure of the optical galaxy center. These contour lines
encircle the central $r \sim 5''$ region of IC 342, and its structure is found to generally agree with those observed in the optical wavelengths, despite the lower angular resolution of the X-ray data. Moreover, the X-ray diffused emission is elongated along the north-south axis, which is similar to the alignment of the three optical nuclear star clusters. These coincidences suggest that the observed X-ray nuclear emission is associated with the ongoing starburst and the three optical star clusters. However, the newly detected X-ray nuclear source C13 does not coincide with any bright features in the H$\alpha$ image, suggesting that it is not associated with the star formation activities at the galaxy center.

4.1.3. Comparison of X-Ray with Radio Data

For comparisons with the X-ray and optical data, we also obtained Very Large Array (VLA) 2 cm (15 GHz) and 6 cm (5 GHz) radio images of IC 342. The observations and the data reduction procedures have already been described in Tsai et al. (2006). These images have spatial resolutions of 0.3'' at 6 cm and 0.1'' at 2 cm, with a 0.05'' uncertainty in the absolute position of detected sources. The positions of all the radio sources detected in the 2 and 6 cm images are marked in Figures 4 (top) and 5 (top). The optical images of IC 342 presented in Tsai et al. (2006) were not astrometrically registered for comparison with the radio images. However, our current analysis presents improved astrometry on the X-ray and optical data, allowing accurate identifications of radio counterparts for the X-ray and optical sources. Our revised astrometry explains the slight differences in the radio source positions of our Figures 4 and 5 compared to Figure 2 of Tsai et al. (2006).

The brightest radio source, source A using the naming scheme of Tsai et al. (2006), is near the optical star cluster SC1 and was identified as a supernova remnant. One of the radio sources, source J, lies very close to the center of the optical emission from NSC at a distance of 0.4'' and a distance of 0.5'' from the center of the nuclear X-ray source C12. This source is very weak, with only a 1.4 $\sigma$ detection in 2 cm, and was actually not detected in the 6 cm data. Tsai et al. (2006) explained source J as a H$\alpha$ region situated between the SC1 and NSC, requiring the excitation from

![Figure 4](image1.png)  
**Fig. 4.** — HST V-band image of the central $19'' \times 16''$ region of IC 342 displayed in square root scale to bring out the features. Top: Locations of the three optical star clusters (black dashed circles). The centroids of the X-ray center sources C12 and C13 (blue crosses) and a 4'' diameter region centered on C12 (blue dashed circle) are also shown. Radio sources detected in the VLA 2 and 6 cm maps are marked (red crosses) and labeled according to the naming convention by Tsai et al. (2006). Bottom: Overlay of Chandra X-ray (blue; same as Fig. 2) and radio 6 cm contours (red) on the optical data. Contour levels of the radio 6 cm flux are 0.37, 0.93, 1.49, 2.05, and 2.61 mJy beam$^{-1}$.

![Figure 5](image2.png)  
**Fig. 5.** — Same as Fig. 4, except that the background image is HST H$\alpha$. 

![Figure 6](image3.png)
a star cluster powered by at least 70 O7 stars. However, with our corrected astrometry, source J was found to be much more likely to be associated with the center of the NSC. We will discuss the possibility of radio emission from a radio-quiet AGN in § 5.2. It should also be noted that none of the radio sources identified as H ii regions by Tsai et al. (2006), except source J, could be associated with any star clusters in the optical images. This could be due to the high internal extinction A_V in the central regions of IC 342, consistent with the presence of high molecular gas concentrations, which could fuel more star formation in the region.

The radio contours from the 6 cm VLA image are overlaid on the HST image and Chandra contours in Figures 4 (bottom) and 5 (bottom). The morphology of the radio emission in the central region is very different from both the X-ray and optical images. C12 is encompassed by several radio sources aligned from northeast to southwest that have been identified as supernova remnants and H ii regions (Tsai et al. 2006). The majority of the bright radio sources and the diffused radio emission are located west of C12, suggesting enhanced star-forming activity in that region.

On the other hand, the faint X-ray source C13 is about 3′′ from a compact H ii region (source L in Tsai et al. 2006). We noticed that the position of source L listed in Tsai et al. (2006) was incorrect; the revised position should be R.A. = 03h46m49.13s, decl. = +68°05′46.4″ (C.-W. Tsai 2007, private communication), which was used here. With the pointing accuracy of the Chandra data at ≈0.5″, we concluded that C13 is unlikely to be associated with any radio emissions.

### 4.2. Variability of the X-Ray Nuclear Source Luminosity

To investigate the long-term variability of the nuclear source C12, we compared the observed X-ray luminosities at the center of IC 342 over a period of 13 yr using data taken by Chandra (this paper; 2006 April 2), XMM-Newton (B03, K03; 2001 February 11), and ROSAT (Bregman et al. 1993; 1991 February 13). We could not directly compare luminosities from the literature because of the different assumptions made in those works. For example, the luminosity values in the earlier ASCA and ROSAT publications were computed assuming a distance to IC 342 of 4.5 Mpc. We recalculated the luminosities from all the observations by using the same energy range, spectral model, and assumed distance of IC 342. Thus, instead of quoting from the literature, we extracted the fluxes of C12 from the archival data of XMM-Newton and ROSAT, together with our Chandra observation, and analyzed them with the procedures described in § 3.2. The fluxes from the different observatories were converted from source counts using the spectral model derived from XMM-Newton since it had the highest spectral resolution. We adopted the simpler spectral model assumed for C12 (named X21) in K03, i.e., a power-law model 

\[ N_{\text{H}} = (0.32 \pm 0.05) \times 10^{22} \text{ cm}^{-2} \] and a power-law model with \( \alpha = 1.72 \pm 0.08 \).

\[ C3 - \text{Power-law model with } N_{\text{H}} = 0.60^{+0.06}_{-0.05} \times 10^{22} \text{ cm}^{-2} \] and \( \alpha = 2.53 \pm 0.16 \). Furthermore, we scaled the luminosities and their errors to a distance of 1.8 Mpc and to the same energy range as HRC-I (0.1–10 keV). The scaled luminosities and errors of the nuclear source C12 from the different X-ray missions are listed in Table 2. The results from the two brightest X-ray sources in our Chandra image, C3 and C6, are also listed for reference. The spectral models used were as follows:

\[ C3 - \text{Power-law model with } N_{\text{H}} = 0.60^{+0.06}_{-0.05} \times 10^{22} \text{ cm}^{-2} \] and \( \alpha = 1.72 \pm 0.08 \).

\[ C6 - \text{Disk blackbody model with } N_{\text{H}} = 1.81^{+0.29}_{-0.25} \times 10^{22} \text{ cm}^{-2} \] and \( kT = 2.00^{+0.24}_{-0.21} \text{ keV} \).

We note that there was an ASCA observation taken in 1993 September. However, the poor spatial resolution of ASCA (FWHM > 1′) and the large extraction radius (2′) used in analyzing the nuclear source (Okada et al. 1998) implies that the ASCA results might suffer from confusion problems. In our Chandra data, a 2′ circular region centering on C12 would have included six other sources (C9, C10, C13, C14, C15, and C18). Using the present Chandra photometric information, we estimated that 46% of the measured ASCA counts of C12 could be due to confusion, implying a 0.1–10 keV luminosity of 11.8 \times 10^{38} \text{ erg s}^{-1}. However, this estimate did not include uncertainties due to long-term spectral and flux variability information of all these X-ray sources. As a result, we did not include the ASCA data point in the present variability study. On the other hand, although the spatial resolutions of ROSAT and XMM-Newton were lower than Chandra, the confusion problem in the two observations were not as significant as that in ASCA. The spatial extent of C12 was similar in both XMM-Newton and ROSAT, about 8″–10″, and a circular region of this size would include both C12 and C13.

Nonetheless, the source counts of C12 are only 6% of C12, and thus its contribution is negligible unless it significantly varies in flux. Thus, we decided to ignore the confusion effect in the XMM-Newton and ROSAT data.

This analysis is the first to study the luminosity of C12 over a long period of time. In the energy range 0.1–10 keV, the observed luminosity of the IC 342 nuclear X-ray source C12 varies roughly by a factor of 2 over the three observations spanning a period of over 15 yr. The observed variations of the luminosity of C12 are actually the smallest among the three X-ray sources investigated. It is worth noting that the flux uncertainties tabulated in Table 2 only include photon statistics. Uncertainties in the relative calibration of various X-ray detectors have not been included. However, previous studies indicate that variations of normalized flux in different X-ray instruments are small, at a level of ±10% (Snowden 2002), and thus are not expected to account for all the flux variations.
variability observed. Another uncertainty in the current study is the assumption of a single spectral model of C12 over the entire period as there was no spectral information from the Chandra and ROSAT data.

We also studied the short-term variability of C12. We extracted the source and background light curves of C12 using dmextract, and high-level background intervals were filtered. The short-term light curves of C12 were studied. However, we were not able to detect any short-term variability on the timescale of the observation because of the observed low count level.

5. NATURE OF THE NUCLEAR X-RAY EMISSION

The high-resolution Chandra HRC-I observation resolves for the first time the X-ray emission at the center of IC 342, revealing the structure of the nucleus of this starburst galaxy. As seen from Figures 4 and 5, both the X-ray and the optical emission are confined to a region of radius ~100 pc in the center of IC 342. The most intense X-ray emission (inner 4") is coincident with the NSC seen in both H\alpha-band and H\alpha images. There are many regions of star formation within the central region of IC 342 which were clearly visible in H\alpha. It is this region that contains the three optical star clusters and includes our detected Chandra X-ray source C12. The extension seen in the X-ray diffuse emission of C12 is most probably due to starburst activities induced by star clusters and massive stars. This region also contains radio sources which align from northeast to southwest. As discussed in Tsai et al. (2006) these radio sources could be interpreted as H ii regions which were small clusters that required excitation by individual O star clusters, each with over 5000 O stars (Becklin et al. 1980; Turner & Ho, 1983). Possible contributors to the X-ray emission from a nuclear starburst include supernovae, O stars, high-mass X-ray binaries (HMXBs), ULXs, and an obscured AGN. Using our Chandra X-ray data, we attempt to explain in the following the stellar nature in the NSC.

5.1. Contributions from Star Formation Activities

Many previous infrared observations of IC 342 (Böker et al. 1997; Schinnerer et al. 2003; Meier & Turner 2005) have proposed a starburst scenario for the nuclear region. The model of the central starburst includes a nuclear star cluster surrounded by a mini spiral arms–ring system on the scale of ~30" (e.g., Fig. 10 in Meier & Turner 2005), as supported by observations of molecular line emissions. The X-ray image generally agrees with the spatial scales of this model, with the size of the C12 emission ~15" x 10" being roughly the size of the proposed central ring (~12"), while the mini spiral arms that extend in the north-south direction to ~45" would be beyond the spatial extent of C12 [see Fig. 1 of Meier & Turner (2005) for a comparison of the optical and 12CO(1–0) infrared emission]. This model suggests that most of the star formation occurs in the central ring region rather than along the spiral arms. Our Chandra observation is consistent with this scenario since the X-ray emission is concentrated in the central 100 pc. This star formation structure is smaller in size compared to those in other starburst galaxies, which have radii of the order of 1 kpc (Böker et al. 1997).

We could study the starburst properties of IC 342 using the results from starburst galaxies and the AGN survey of Mas-Hesse et al. (1995) with the far-infrared to soft X-ray luminosity ratio. The far-infrared flux measured by the Infrared Astronomical Satellite (IRAS) at 60 \mu m was F_{\text{60 \mu m}} = 260 \pm 20 Jy in the inner r = 16" region of IC 342 (Beck & Golla 1988). Tsai et al. (2006) found that the luminosity of the compact H ii regions in the nucleus was of the order of ~5%–10% of the total IR luminosity of IC 342. Therefore, we estimated the far-infrared flux in the galaxy center of IC 342 to be F_{\text{60 \mu m}}(C12) ~ 13–26 Jy. We derived the soft (0.5–4.5 keV) X-ray flux of C12 with WebPIMMS using the spectral model and parameters listed in § 3.2 and obtained L_{\text{0.5–4.5 keV}} = (1.9 \pm 0.3) \times 10^{38} \text{ erg s}^{-1}, leading to \log(L_{\text{0.5–4.5 keV}}/F_{\text{60 \mu m}}) flux ratio in the range ~3.1 to ~3.4. This is in agreement with the value for star formation galaxies, ~3.33 (\sigma = 0.47), and slightly smaller than the average value of Seyfert 2 galaxies, ~2.54 (\sigma = 0.81; Mas-Hesse et al. 1995).

Ward (1988) derived a model to predict X-ray emission from starbursts using the Br\gamma emission. The model suggests that the X-ray emission arises from the accretion of material in Population I binary systems which are formed together with the OB stars. The total X-ray emission in the starburst is calculated to be

\[ L_{\text{0.5–3 keV}} = 7 \times 10^{-35} \frac{L_{\text{Br\gamma}} L_{\text{Xbin}}}{R} \text{ (erg s}^{-1}), \]

where \( L_{\text{Br\gamma}} \) is the observed Br\gamma emission, \( L_{\text{Xbin}} \) is the average X-ray luminosity of binary systems and was assumed to be 10^{38} \text{ erg s}^{-1}, and \( R \) is the number of OB stars per massive binary system and was assumed to be 500 (Fabbiano et al. 1982). The Br\gamma emission from the inner 100 pc of IC 342 was measured to be \( \approx 6.5 \times 10^{37} \text{ erg s}^{-1} \) (Böker et al. 1997), thus implying a predicted X-ray luminosity from the starburst of \( L_{\text{0.5–3 keV}} = 9.1 \times 10^{38} \text{ erg s}^{-1} \). Our observed 0.3–5 keV X-ray luminosity of C12 is about 20% of this predicted luminosity. This might suggest that the X-ray emission from the starburst component in C12 was not dominated by Population I binary systems as suggested in the Ward (1988) model. It might instead be due to thermal emission such as coronal from young stars, supernovae/supernova remnants, and the hot interstellar medium heated by supernovae and stellar winds. This might suggest that the soft X-ray emission in C12 was due in part to the starburst component and part to some other thermal emission. We will discuss the possible thermal origin of the diffuse emission from C12 in § 5.3.

5.2. Contributions from AGN

Another possible origin of the core X-ray emission from the galactic center is an AGN. Using the XMM-Newton data, B03 proposed that the hard X-rays from C12 could be coming from a hidden AGN, although there was no direct evidence to confirm its existence in IC 342. The starburst-AGN connection has been a topic that generated great interest, but the exact relationship remains uncertain. The triggering mechanism for both phenomena could be the interacting or the merging of gas-rich galaxies, which generates fast compression of the available gas in the inner galactic regions, causing both the onset of a major starburst and the fueling of a central black hole, hence raising the AGN. Examples of this class of objects include NGC 6240 (Lira et al. 2002), NGC 4303 (Jiménez-Bailón et al. 2003), and NGC 1808 (Jiménez-Bailón et al. 2005). One particularly interesting object for comparison is NGC 1808, where a similar core + diffuse X-ray emission morphology was observed. The extended X-ray emission of the NGC 1808 center (~850 pc) is dominated by soft radiation (~1 keV) and follows the same orientation as the H\alpha and optical-UV emission, suggesting intense star formation in the region. In contrast to IC 342, two X-ray point sources (with a separation of ~65 pc) were resolved in the core of NGC 1808. Spectral information from the Chandra ACIS data showed that they were associated, respectively, with hot gas emission and hard X-ray emission. The nuclear location from the 2MASS data of NGC 1808 was closer to the softest point source (source S1 in Jiménez-Bailón et al. 2005). Furthermore, both of the X-ray spectra of the centers of IC 342 and NGC 1808 can be modeled with absorbed power law.
law + MEKAL models, and the Fe Kα emission is missing in both spectra. Jiménez-Bailón et al. (2005) compared the ratios of the detected lines such as O viii and Ne ix in NGC 1808 with those observed in M82 and concluded a starburst-AGN coexistence in NGC 1808.

With astrometrically corrected X-ray and radio data, we were able to study the radio loudness of the possible AGN at the center of IC 342. As discussed in §4.1.3, radio observations of IC 342 reveal a group of weak sources within a $5\prime\prime$ radius of the center, with an integrated $L_\text{6 cm} \approx 10^{35.6}$ erg s$^{-1}$. This is slightly lower than the range of $10^{36} - 10^{39}$ erg s$^{-1}$ observed from the 48 low-luminosity AGNs (LLAGNs) sampled by Terashima & Wilson (2003). A weak radio source, source J, is near the X-ray center source C12, with $F_\text{2 cm} = 0.7 \pm 0.5$ mJy and $F_\text{6 cm} < 0.2$ mJy ($3\sigma$ limit), while a stronger source, source A, with $F_\text{2 cm} = 0.9 \pm 0.3$ mJy and $F_\text{6 cm} = 1.5 \pm 0.2$ mJy, is 0.99$^\alpha$ away from C12 (Tsai et al. 2006). Therefore, if we concentrate on the central $2\prime$ radius region of IC 342, corresponding to the size of the core component of C12, then the integrated radio flux in the region would be $\sim 1 \times 10^{16}$ erg cm$^{-2}$ s$^{-1}$. Together with the hard (2–10 keV) X-ray flux of the C12 core determined from WebPIMMS ($F_\text{WebPIMMS} = 9.1 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$), we could determine the radio loudness parameter $R_X = L_\text{6 cm}/L_\text{2–10 keV}$ as defined by Terashima & Wilson (2003) to be $\log R_X \approx -3$. This value is comparable to the average for Seyfert galaxies ($-3.3^{+0.5}_{-0.9}$) as determined from a sample of 51 AGN candidates (Capetti & Balmerande 2006).

Based on the distribution and flux of the radio sources in the nucleus, we could classify IC 342 as a radio-quiet AGN, if there existed one. Radio-quiet AGNs include LINERs, Seyfert (1 and 2) galaxies, and QSOs (Capetti & Balmerande 2006). Assuming the X-ray luminosity of C12 were due entirely to an AGN, then the hard X-ray luminosity observed, $L_\text{2–10 keV} = (5.4 \pm 0.5) \times 10^{32}$ erg s$^{-1}$, would be just below the lower range of other LINERs observed with ROSAT, ASCA, and Chandra (in the range $10^{38} - 10^{41}$ erg s$^{-1}$), but would be low when compared to Seyfert 1 galaxies or quasars (typically $>10^{43}$ erg s$^{-1}$). Another property to consider is the X-ray flux variability. As shown in Table 2, we observed the IC 342 center X-ray flux to have varied by a factor of $\sim 2$ (or flux variability amplitude of $\sim 60\%$) over 15 yr in the three observations, which is comparable to the mean long-term flux variability amplitude of 68% for type 1 AGNs and 48% for type 2 AGNs (Beckmann et al. 2007).

On the other hand, we also notice that the power-law index of the X-ray central source determined from the XMM-Newton spectral fit, $\alpha = 2.53 \pm 0.16$ (K03), is slightly steeper than the typical value of radio-quiet AGNs and LINERs at $\alpha = 1.7 - 2.3$ (Reeves & Turner 2000; George et al. 2000; Georgantopoulos et al. 2002). Moreover, the absorption column density, $N_\text{H} \sim 10^{22}$ cm$^{-2}$ (B03; K03), is much lower than typical AGN values of $N_\text{H} \sim 10^{24}$ cm$^{-2}$, together with no intrinsic absorption in the X-ray spectral fit. There was also no sign of the 6.4 keV Fe Kα line emission, typically an indicator of AGNs, in the XMM-Newton EPIC spectrum (B03; K03). However, this line is also absent in a number of starburst galaxies identified as having hidden AGNs (Tzanavaris & Georgantopoulos 2007), and thus we cannot exclude the possibility of the presence of an AGN in IC 342. The positional coincidence of the X-ray center with the optical star clusters in IC 342 could suggest a scenario of coexistence of the nuclear star cluster and an AGN, as discussed by other authors (Seth et al. 2008; Shields et al. 2008). We attempt to place a lower limit to the black hole mass. Assuming that the black hole is accreting at a sub-Eddington rate, we could place a lower limit of the black hole mass at the center of IC 342 at $M_\text{BH} \geq 3 \times 10^4 M_\odot$ given the bolometric luminosity of the galaxy $L_\text{bol} \approx 3 \times 10^{42}$ erg s$^{-1}$ as determined by Becklin et al. (1980). On the other hand, it had been reported that nuclear star clusters are more massive than the coexisting black holes and their mass ratio $M_\text{BH}/M_\text{NSC} \sim 0.1 – 1$ (Seth et al. 2008). This implies $M_\text{BH} \leq 6 \times 10^6 M_\odot = M_\text{NSC}$, the nuclear star cluster mass as determined by IR data by Böker et al. (1999). Another estimate of the black hole mass comes from the $M_\text{BH} – \sigma_\text{bulge}$ relation (Gebardt et al. 2000; Tremaine et al. 2002; Hu 2008), which had been shown to apply even in the massive star cluster regime (Gebardt et al. 2005; Shields et al. 2008). Using the velocity dispersion measurements for the nuclear star cluster ($\sigma_\text{NSC} = 33$ km s$^{-1}$; Böker et al. 1999), and the $M_\text{BH} – \sigma_\text{bulge}$ relation of Gebhardt et al. (2000), we derived $M_\text{BH} \approx 1 \times 10^5 M_\odot$, which is consistent with the limits described above. Based on these calculations, the range of black hole mass is suggestive of an IMBH. However, we should not rule out the alternative possibility of an inactive supermassive black hole (mass $\sim 10^9 – 10^7 M_\odot$) similar to known Seyfert nuclei in which the nuclear emission is due to advection-dominated accretion flows (ADAFs; Rees et al. 1982; Narayan & Yi 1995; Fabian & Rees 1995). Further spectral analysis could help to address whether this is the case.

5.3. Other X-Ray Contributions Associated with Star Formation

The spatial extent of the X-ray emission from the nucleus of IC 342 could alternatively indicate the presence of populations of stellar objects uniformly distributed throughout the core region. These objects could be X-ray binaries, OB stars, or supernova remnants. For example, as pointed out by Stevens et al. (1999) populations of massive X-ray binaries (XRBs) evolved from high-mass stars could be formed in starburst events, and such populations would be consistent with models associated with starbursts. It had been suggested that photoionization from these stars might have accounted for the enhanced C$^+$ millimeter emission in the central ring of the mini spiral model of IC 342 (Meier & Turner 2005).

We considered the possibility of multiple unresolved point sources, consisting of a mixture of stars and XRBs in the nuclear star cluster, contributing to the observed X-ray structure at the center of IC 342. A burst of star formation usually resulted in the production of a large number of OB stars (Stevens et al. 1999). With the typical X-ray luminosity for O stars $\approx 10^{31} – 10^{32}$ erg s$^{-1}$ (Sciortino et al. 1990) and the number of O stars in the nucleus of IC 342 at $\sim 4000$ estimated from the Brγ emission (Ward 1988), we derived the X-ray luminosity from these stars at $L_\text{X} \approx 34.6 – 35.6$. This is less than 0.1% of the total observed X-ray luminosity of C12. The more luminous HMXBs, usually associated with a young stellar population like O stars, might have also contributed to the observed X-ray emission. This may be inferred from the ratio of the total X-ray luminosity from HMXBs (with $L_\text{X} \approx 10^{37} – 10^{38}$ erg s$^{-1}$) to the number of O stars, i.e., $(2–20) \times 10^{34}$ (Helfand & Moran 2001). For the nucleus of IC 342, $L_\text{O,bin}$ was estimated to be about $8 \times 10^{37} – 10^{38}$ erg s$^{-1}$ (10%–90% of the X-ray luminosity of C12), and the corresponding number of X-ray binaries was about 10 as inferred from $L_\text{O,bin}$. If these O stars and XRBs were uniformly distributed in a region of radius 50 pc (the central 4′′ region of C12), the mean separation ($<0.5''$ for HMXBs and $<0.01''$ for O stars) would be smaller than the spatial resolution of the Chandra HRC-I. As a result, a model with 4000 O stars and $\approx 10$ HMXBs could account for both the observed morphology and the flux of the core component of the X-ray emission of C12.

We also considered whether the diffuse component of C12 could also be explained by the model above. As shown in Figure 5, the nucleus contains many regions of star formation, which could
be the result of an outflow induced by the stellar winds of the massive stars or X-ray binaries present in the star clusters, as observed in M82 (Strickland et al. 1997; Moran & Lehnert 1997). The exact nature of this diffuse emission remains uncertain given the limited amount of X-ray data available. Further observations with possible spectral analysis of this diffuse emission could help to link the starburst activities and the X-ray emission of the stellar objects in the nuclear star cluster.

6. SUMMARY AND CONCLUSION

This paper aims to study the nature of the X-ray emission in the nucleus of IC 342 using a high-resolution (θFWHM ≈ 0.5″) Chandra HRC-I observation. The historical ULX at the center of IC 342, X3, was resolved into two sources, namely, C12 and C13, for the first time, since the X-ray telescopes prior to Chandra did not have enough spatial resolution. The brighter source C12, with over 90% of the X-ray nuclear flux, was found to be located very close to the optical galactic center. The source C12 was also revealed as an extended source with a complex X-ray morphology, with a core component of diameter 4 ″ that is roughly consistent with a point source of $L_{0.05-10\text{keV}} = (6.7 ± 0.5) \times 10^{38}$ erg s$^{-1}$ and a diffuse component that extends out to a diameter of ~10 ″, or ~150 pc. Thus, we concluded that C12 is not an ULX. The much weaker source C13, with $L_{0.05-10\text{keV}} = (5.0 ± 1.4) \times 10^{37}$ erg s$^{-1}$, is consistent with a point source situated 6.5 ″ at P.A. = 240 ″ from C12.

Registration of the X-ray image with optical (HST) and radio (VLA) data allowed us to find the counterparts of the X-ray sources. The registered position of C12 is R.A. = 03h46m48.43s, decl. = +68°05′47.45″, which is located 0.53″ from the optical NSC (Boek et al. 1999), 0.50″ from a weak radio source (source J in Tsai et al. 2006), and within the boresight correction of 0.45″ of the Chandra data. Intense star formation was observed in the HST Hα image of the inner 100 pc of IC 342, where the three optical star clusters (SC1, SC2, and NSC) and our Chandra X-ray source C12 are found. Moreover, the diffuse X-ray emission extends preferentially along the north-south direction, which is the same as the alignment of the star clusters in the optical. This suggests that the nuclear X-ray emission is associated with star formation.

We discussed possible contributors to the X-ray emission in the nuclear region of IC 342, with a main focus on the extended source C12. A starburst model for IC 342 based on molecular line observations (Meier & Turner 2005) included a mini spiral arm – ring system was found to be consistent with the spatial extent of C12. Furthermore, the predicted X-ray emission from starbursts as derived from the Brγ emission (Ward 1988) is close to the actual observed X-ray luminosity of C12, indicating that X-ray emission from the nucleus is dominated by starburst activities. On the other hand, the hard emission from the previous XMM-Newton observation suggested that there could be an AGN in IC 342 (B03; K03). The luminosity of C12, $L_{0.08-10\text{keV}} = (6.7 ± 0.5) \times 10^{38}$ erg s$^{-1}$, is consistent with that of a LINER (typical luminosity $10^{38} – 10^{41}$ erg s$^{-1}$). By comparing our current observation with earlier X-ray missions, we found a possible long-term variability factor of 1.8 in the IC 342 nuclear X-ray emission over 15 yr. This amount of variation would be consistent with that from an AGN. Weak radio emission of $L_{6cm} \sim 10^{29}$ erg s$^{-1}$ in the vicinity of C12 is consistent with a radio-quiet AGN. The observed properties (luminosity and absorption column density) are similar to those of type 2 low-luminosity LINERs or Seyfert 2 galaxies. The black hole mass as inferred from the $M_{BH}$-$\sigma$ relation for the AGN of $\approx 1 \times 10^5 M_\odot$ is consistent with an IMBH, but we should not ignore the possibility of an inactive supermassive black hole. In conclusion, our current data did not confirm the existence of an AGN in the core of IC 342, but it could neither be discarded.

The lack of any spectral information in our Chandra HRC-I data did not allow for detailed studies of the surface brightness distribution of the nuclear source C12 in different X-ray energy bands. In particular, separate spectral information on the core and diffuse components of the X-ray galactic center emission of IC 342 would allow us the opportunity to put a tighter constraint on the coexistence of a low-luminosity AGN and a starburst in IC 342. With the X-ray emission from the core and diffused components at roughly the same level, further high spectral resolution observations with the Chandra ACIS could shed new light on how the nucleus of IC 342 fits into the starburst-AGN family.

We thank L. Sjouwerman and C.-W. Tsai for generously providing the radio maps and for helpful discussions. This work is based on observations obtained with Chandra. Support for this work was provided by the National Aeronautics and Space Administration through Chandra award GO6-7110X issued by the Chandra X-Ray Observatory Center, which is operated by the Smithsonian Astrophysical Observatory for and on behalf of the National Aeronautics Space Administration under contract NAS8-03060. S. Y. Mak acknowledges support from HKU under a Postgraduate Studentship grant. C. S. J. Pun acknowledges support of a RGC grant from the government of the Hong Kong SAR. A. K. H. Kong acknowledges support from the National Science Council, Taiwan, through grant NSC96-2112-M-007-037-MY3.
