Genetic polymorphisms have been demonstrated to be associated with vulnerability to human infection. ICAM3, an intercellular adhesion molecule important for T cell activation, and FCER2 (CD23), an immune response gene, both located on chromosome 19p13.3, were investigated for host genetic susceptibility and association with clinical outcome. A case-control study based on 817 patients with confirmed severe acute respiratory syndrome (SARS), 307 health care worker control subjects, 290 outpatient control subjects, and 309 household control subjects unaffected by SARS from Hong Kong was conducted to test for genetic association. No significant association to susceptibility to SARS infection caused by the novel coronavirus (SARS-CoV) was found for the FCER2 and the ICAM3 single nucleotide polymorphisms. However, patients with SARS homozygous for ICAM3 Gly143 showed significant association with higher lactate dehydrogenase levels (P = .0067; odds ratio [OR], 4.31 [95% confidence interval {CI}, 1.37–13.56]) and lower total white blood cell counts (P = .022; OR, 0.30 [95% CI, 0.10–0.89]) on admission. These findings support the role of ICAM3 in the immunopathogenesis of SARS.

Severe acute respiratory syndrome (SARS) caused by the novel coronavirus (SARS-CoV) occurred largely in Chinese communities and in Asian countries [1]. A proportion of persons exposed to the virus without adequate protection, however, did not develop the disease [2]. It has been reported that of the close contacts of all 1755 patients with SARS diagnosed and treated in Hong Kong, only 14% actually died of the disease; the reason for this has yet to be discovered. Genetic polymorphisms have been demonstrated to be associated with vulnerability to a variety of human infections, including SARS [3]. Association between susceptibility to SARS and the major histocompatibility complex (MHC) class I has also been reported (e.g., the HLA-B*4601 allele [4] and HLA-B*0703 allele from Hong Kong [5]). However, the subject numbers in both these studies had been small. The angiotensin-converting enzyme–2 (ACE2) is the only known functional receptor for SARS-CoV infection/replication [6], but no significant association for susceptibility or clinical outcome has been shown with the polymorphisms of the ACE2 gene [7]. DC-SIGN (dendritic cell [DC]–specific intercellular adhesion molecule-3 [ICAM3]–grabbing nonintegrin, encoded...

by CD209) is an important C-type lectin expressed on DCs that can bind pseudovirus transfected by the SARS spike gene [8, 9]. L-SIGN (liver/lymph node–specific ICAM3 grabbing nonintegrin, encoded by CLEC4M) is a homologue of DC-SIGN and is also a binding receptor for SARS-CoV infection [10]. Interestingly, DC-SIGN, L-SIGN, and FCER2 ICAM3 genes are all mapped on 19p13.3, within 71 kb of each other, and belong to the C-type lectin family [11], whereas ICAM3 is the natural ligand for both DC-SIGN and L-SIGN [12, 13].

ICAM3, being expressed constitutively on T cells and other leukocytes, is a potent signalling molecule and a major ligand in the initiation of T cell–mediated immune responses [14, 15]. In addition to the recognition of peptide/MHCs on the surface of professional antigen presenting cells (APCs), such as DC [16], by the T cell receptors on the T cell surface, the interaction of adhesion molecules between the APCs and T cells are also critical for activating antigen-specific T cells [17]. The binding between ICAM3 and its ligands DC-SIGN or leukocyte function–associated antigen–1 [18] provides transient engagement of naive T cells with DCs, which then allows the T cells to sample large numbers of MHC molecules for the presence of specific peptides [19]. This initial cell-to-cell engagement step is critical for induction of T cell responses, which in turn play a central role in the immunoregulation of infectious diseases. It is noteworthy that circulating forms of ICAM3 have been used as a parameter to monitor disease progression, particularly in HIV-infected patients [20]. However, the role of ICAM3 in settings of other viral infection, such as SARS-CoV infection, is still unknown.

As the association between specific MHC alleles and susceptibility to SARS has been observed, we hypothesized that polymorphisms of other related molecules such as ICAM3, FCER2, DC-SIGN, and L-SIGN may influence susceptibility to SARS-CoV infection. We have previously shown that individuals homozygous for the tandem neck repeats of L-SIGN (CLEC4M) gene are less susceptible to SARS infection [21]. In the present case-control genetic association study, we report that the Gly143 polymorphism of ICAM3 are associated with higher lactate dehydrogenase (LDH) levels and lower total white blood cell (WBC) counts on admission in patients with SARS-CoV infection.

PATIENTS, MATERIALS, AND METHODS

Subjects were recruited for this study after approval from the respective institutional review boards of hospitals involved. Informed signed consent was obtained from subjects donating 6 mL of peripheral blood.

Patients with SARS. The initial study included 309 patients with confirmed SARS recruited from 3 major hospitals that treated patients with SARS in Hong Kong during the 2003 outbreak, namely, Pamela Youde Nethersole Hospital, Princess Margaret Hospital, and United Christian Hospital. Subsequently, we further recruited 508 patients with SARS from SARS follow-up outpatient clinics in the 3 previously mentioned hospitals and 3 others, namely, Queen Mary Hospital, Alice Ho Miu Ling Nethersole Hospital, and Prince of Wales Hospital. All 817 patients with SARS were confirmed by serologic analysis and/or reverse-transcriptase polymerase chain reaction (PCR). Their clinical data were retrospectively obtained from Hospital Authority, Hong Kong, with permission from all attending clinicians of the respective hospitals. These included age; sex; length of hospital stay; treatment in an intensive care unit (ICU) and duration of ICU treatment; whether patients required assisted ventilation, steroid treatment, pulse steroids, or intravenous immunoglobulin (IVIG); and final outcome in terms of survival and death. Because most of the patients were recruited from the SARS follow-up clinics after discharge, the proportion of deaths was small and could not be used as a measure of outcome. Results of hematological and biochemical laboratory investigations on admission were also retrieved. These included hemoglobin level, absolute lymphocyte count,
The nsSNP for \textit{FCER2} SNPs for \textit{ICAM3} Gly143, \textit{FCER2}, \textit{DC-SIGN}, and \textit{L-SIGN} were identified from the National Center for Biotechnology Information dbSNP database (http://www.ncbi.nlm.nih.gov/projects/SNP/). We specifically looked for nsSNPs that may result in structural changes of the encoded protein leading to functional effect, as well as 3′UTR SNPs. At the time the study was initiated, no nsSNPs or 3′UTR SNPs were reported for \textit{DC-SIGN}. Allele frequency of the SNPs was first evaluated in 90 unaffected healthy individuals, and only those with minor allele frequency >5% were further investigated. Five SNPs for \textit{FCER2} and 1 for \textit{ICAM3} were thus selected for study. The nsSNP for \textit{L-SIGN} with minor allele frequency <5% was not further investigated.

\textbf{Genotyping by Sequenom.} Genotyping of the initial SARS samples (309 cases) and HCW control subjects was done by Sequenom. MassARRAY AssayDesign software (Sequenom) was used to design amplification and allele-specific extension. PCRs were performed in 384-well plate format, and the amplified products were treated with alkaline phosphatase. The final allele-specific base extension was performed and then treated with SpectroClean (Sequenom) resin. Extended products were dispensed onto SpectroCHIP (Sequenom), separated by Brucker Autoflex MALDI-TOF mass spectrometer (Brucker) and analyzed by SpectroTYPER (Sequenom). In every plate assayed, there was 1 well for blank control and 5 wells for duplicate check on 5 samples for quality control.

Genotyping of the additional SARS samples and HHC and OPC group samples for the \textit{ICAM3} Gly143 SNP was performed by Allelic Discrimination TaqMan Assay (assay C\_15974025\_10;...

NOTE. The total no. of cases successfully genotyped for each single nucleotide polymorphism varied, depending on the success call rate generated from the MassARRAY Analyzer (Sequenom). Bold type indicates statistically significant values. CI, confidence interval; HCW, health care worker; HWE, Hardy-Weinberg equilibrium; OR, odds ratio; SARS, severe acute respiratory syndrome.

* OR was obtained by comparing combined Gly-allele carriers with homozygous Asp carriers.

Applied Biosystems). The assay was performed according to conditions as described elsewhere [22]. Each 96-well plate reaction contained 1 negative control, controls for each genotype that was examined by direct sequencing, and there were 8 replicated samples.

**Risk association analysis.** Genotype distributions of the patient group and the control groups were assessed using the χ² test using SPSS for Windows (version 13.0), and odds ratio (OR) and 95% confidence intervals (CIs) were used to measure strength of association. Hardy-Weinberg equilibrium (HWE) and pair-wise linkage disequilibrium (LD) analysis were calculated using the χ² test, taking P < .05 for the level of significance. Haplotype frequencies were estimated using Arlequin (version 2.00; Genetics and Biometry Laboratory, University of Geneva) based on expectation-maximization algorithm. The standardized LD parameter (D') was evaluated by 2LD [23]. Because a significant proportion of the HHC subjects recruited were genetically related to each other, we also used logistic regression with the cluster and robust methods (STATA program; version 9; StataCorp) [24] to factor in genetic relations of all subjects.

**Analysis for association with clinical outcome.** The χ² test was used to test for possible association with nominal clinical outcome measures such as those requiring ICU care and/or ventilation, requiring pulse steroid and/or IVIG treatment. For the analysis of numerical variables such as length of hospital stay and length of ICU stay, and hematological and biochemical laboratory indices, each of these parameters was first analyzed by Student’s t test to compare the mean values of patients having wild-type versus the variant genotype. Because of the variations in the reference ranges of biochemical indices used by different hospitals, some of the values, such as LDH, alanine aminotransferase, and creatinine kinase, were standardized by dividing the actual values by the upper limit of normal reference range. For the final analysis, the values were arranged in ascending order forming a curve that fits a polynomial trend line. The cutoff value was taken at the inflection of the curve or at the point when the values begin to change exponentially.

**RESULTS**

**Demographic data.** The demographic features of the patients with SARS and the various control groups are summarized in...
ICAM3 Variant Associated with SARS

Figure 1. Preliminary studies. A, Genotype and allele frequencies of ICAM3 of patients with severe acute respiratory syndrome (SARS) with normalized lactate dehydrogenase (LDH) levels on admission (as ratio to upper limit of normal reference range). B, Genotype and allele frequencies of ICAM3 of patients with SARS with white blood cell (WBC) count on admission.

Table 1. The clinical features are as summarized in Table 2. In HCW control subjects, there were 269 (87.6%) who had worked in a SARS ward/SARS ICU, and the remaining 38 (12.4%) worked either in a suspected SARS cohort ward or in a general ward that had cared for patients with SARS. They had worked in these environments for 4–120 days (median, 50 [average, 52] days) during the SARS outbreak, and 178 (58%) had performed high-risk procedures. The 290 OPC subjects had previously been used in our genetic association study of L-SIGN for susceptibility to SARS [21]. However, only 260 cases had sufficient DNA left over for further analysis. The third control group of 309 HHC subjects was recontacted from the study of Leung et al. [2]. These consisted of asymptomatic close contact of patients with SARS who were serologically negative for SARS. Their relationship to the patients with SARS recruited is as summarized in Table 3.

Genotype analysis of initial sample of 309 patients with SARS and 307 HCW controls. The genotype and allele frequencies of each of the polymorphisms studied on the initial cohort of 309 patients with SARS and 307 HCW controls are summarized in Table 4. Genotypes were found to be in HWE for both the SARS and control populations for all FCER2 and ICAM3 SNPs, except for the ICAM3 Asp143Gly SNP (rs2304237) in the HCW population. This SNP was included in our statistical analysis for genetic association because it might be representing a preselected group with overrepresentation of protective genotype, accounting for Hardy-Weinberg disequilibrium. Genotype frequency analysis showed that the ICAM3 Asp143Gly SNPs were found to have significant risk association for susceptibility to SARS ( \( P = .001, \chi^2 \) test; OR, 2.17 [95% CI, 1.35–3.52]), with Gly-allele carriers being more at risk for SARS. Allelic association was also noted ( \( P = .009, \chi^2 \) test; OR,
The risk association of ICAM3 Asp143Gly SNP was based on genotyping data for which the control group deviated from HWE, we further tested for this association using other control groups. Although the OPC subjects may not necessarily have been exposed to SARS-CoV, the HHC subjects would have had similar chance of exposure to SARS-CoV as the HCW control subjects. Genotype data of both OPC and HHC groups were in HWE. However, no significant difference in genotype or allele frequency distribution was found between the initial 309 SARS samples with neither the HHC group nor the OPC group (data not shown). No significant difference was also found comparing these 2 control groups with the final SARS sample size of 817 cases (table 7). From this further analysis, it should be concluded there is no association of the ICAM3 Asp143Gly SNP with susceptibility to SARS infection.

The genotype data of the ICAM3 Asp143Gly SNP for the 817 SARS cases was further analyzed for possible association with LDH levels and WBC counts previously suggested in the initial SARS samples. Student’s t test showed similar findings as that of the initial samples. The cutoff values for LDH levels for χ^2 test were 1.6, dividing the patient into low LDH and high LDH level groups, whereas that of WBC count was 4.5 (figure 2A and 2B and tables 8 and 9). For LDH level, the χ^2 test for overall genotype gave P = .015 and homozygous Gly versus homozygous Asp gave P = .0067 (OR, 4.31 [95% CI, 1.37–13.56]). Allelic association was also observed (P = .0093; OR, 1.75 [95% CI, 1.14–2.67]). All P values remained significant after multiple testing correction (n = 2) (adjusted P = .025), thus confirming the association for LDH level on this large

**NOTE.** Data are no. (%), unless otherwise indicated. Bold type indicates statistically significant values. CI, confidence interval; OR, odds ratio.

^a Normalized LDH levels on admission were less than the cutoff value (1.2).

^b Normalized LDH level on admission were higher than the cutoff value (1.2).

^c χ^2 test (3 × 2 table) for overall genotype.

^d Lower LDH, n = 148; higher LDH, n = 14.

There was no significant association found for nominal clinical outcome measures such as those requiring ICU care and/or ventilation, requiring pulse steroid and/or IVIG treatment for all the FCER2 and ICAM3 SNPs studied. Other numeric clinical parameters showed no significant association for the 4 FCER2 SNPs (P > .05, Student’s t test). For the ICAM3 Asp143Gly SNP, however, borderline association for LDH level was observed (P = .046, comparing homozygous wild-type Asp versus Gly-allele carriers). An overall significant association (P = .013, χ^2 test) was observed; homozygous Gly versus homozygous Asp gave P = .017 (figure 1A and table 5). For WBC count, Student’s t test gave P = .005 for homozygous Gly versus homozygous Asp. An overall significant association was found (P = .007, χ^2 test); homozygous Gly versus homozygous Asp gave P = .012 (χ^2 test). However, the number of cases with the homozygous Gly was too small for this significance to be valid (figure 1B and table 6). Moreover, all these values become nonsignificant after multiple testing correction for the number of laboratory indices analyzed (n = 13) (adjusted P = .0039).

NOTE. In part A, patients who were blood related were excluded from analysis; genotype χ² test was performed using TT (Asp) genotype or T (Asp) allele as reference. In part B, logistic regression model and robust cluster method were performed using STATA program (version 9). CI, confidence interval; OR, odds ratio.

sample size. Association for WBC count was also demonstrated for homozygous Gly versus homozygous Asp (P = .022; OR, 0.30 [95% CI, 0.10–0.89]), which remained significant after multiple testing correction (adjusted P = .025). It is important to note that the homozygous Gly genotype associated with higher LDH levels was associated on the other hand with lower WBC counts.

**DISCUSSION**

In this large genetic association study of SARS susceptibility, we compared the genotype of 817 patients with SARS with that of 3 groups of control subjects of 906 unaffected individuals. Although comparison of patients with SARS genotype with that of HCW control subjects suggested risk association for the ICAM3 Asp143Gly SNP, this association could not be confirmed on comparison with the other 2 control groups. The deviation from HWE in the HCW control group is intriguing as it was also observed for the L-SIGN (CLEC4M) tandem-neck repeats we had previously reported [21], for which genotype had been confirmed by Southern blot analysis. In that study, the association observed between SARS and HCW control subjects was confirmed by comparing patients with SARS with outpatient
control and random control subjects, which both showed the same significant association. Because 22% of all patients with SARS in Hong Kong were HCWs [25], we therefore reckon that the unaffected health care workers recruited for study may likely represent a preselected group with overrepresentation of the protective L-SIGN genotype.

Repeated genotyping of 170 cases from the HCW control samples using Allelic Discrimination TaqMan Assay confirmed their ICAM3 genotype, which still deviated from HWE ($P = 8.34 \times 10^{-4}$). Furthermore, $\chi^2$ test analysis comparing the ICAM3 genotypes of the 817 patients with SARS with these 170 HCW control subjects continued to demonstrate significant difference ($P = .003$). In contrast, the genotype and allele frequency distribution of the OPC and HHC groups was very similar to that of the patients with SARS. It is worth noting that the age and sex distribution of both OPC and HHC groups (table 1) is better matched to that of the patients with SARS recruited than to that of the HCW control subjects. However, confounding factors such as age and sex had already been accounted for with the use of logistic regression analysis with adjustment for age and sex (data not shown). The presence of other confounding factors as yet unaccounted for in this HCW population probably gave rise to this apparent association. Thus, with the analysis of 3 control groups, no association of the ICAM3 Asp143Gly SNP with susceptibility to SARS infection can be concluded. On the other hand, genotype analysis of our 817 patients with SARS confirmed the association of higher LDH levels and lower WBC counts with the homozygous Gly143 genotype of ICAM3, which supports the role of ICAM3 in the immunopathogenesis of SARS.

The polymorphism ICAM3 Asp143Gly involves the replacement of a large acidic amino acid aspartic acid by a small neutral amino-acid glycine in the extracellular domain. Although the protein structure of ICAM3 is not yet disclosed, it is postulated to be similar to that of ICAM1 [26], whose structure has been demonstrated [27]. The ICAM3 Asp143Gly SNP is located at...

Figure 2. A, Genotype and allele frequencies of ICAM3 of all patients with severe acute respiratory syndrome (SARS) with normalized lactate dehydrogenase (LDH) level on admission (as ratio to upper limit of normal reference range). B, Genotype and allele frequencies of ICAM3 of all patients with SARS with white blood cell (WBC) counts on admission.
Reduced confounding factors that are difficult to eliminate, such as different hospitals throughout Hong Kong. This may have introduced possible differences in management preferences relating to the length of hospital stay, ICU care, and decision to initiate assisted ventilation and administration of steroids. On the other hand, laboratory parameters were easier to standardize. Other parameters reported to correlate with clinical outcome such as viral load and chest x-ray appearances were only available for a relatively small number of patients.

Although it is generally understood that LDH levels are non-specific reflections of tissue destruction, the finding of associated higher LDH levels with lower WBC counts suggests that raised LDH levels in patients with SARS may also be the result of leukocyte destruction associated with immune response. The finding of decreased peripheral T, B, and NK cells and high levels of plasma proinflammatory cytokines in patients with SARS lend support to this [28, 29]. An increase in LDH levels in the acute phase of SARS infection has been postulated to be possibly related to immune hyperactivity [30]. High peak LDH levels have been reported to be an independent predictor of adverse outcome [31–34]. Thus patients with SARS who are homozygous for CC genotype of the ICAM3 Asp143Gly SNP are associated with a 4-fold chance of higher LDH levels on admission and poorer prognosis. Although the SARS outbreak appears to have been contained, the molecular determinants and pathogenesis of SARS remain unclear. Functional studies to investigate the role of ICAM3 Asp143Gly polymorphism in influencing the initiation of immune response to SARS-CoV infection will contribute toward a better understanding of the pathogenesis of SARS.

d Lower LDH, n = 662; higher LDH, n = 95.
e Lower LDH, n = 1164; higher LDH, n = 190.

The results of this study suggest that, although FCER2 and ICAM3 SNPs are not associated with susceptibility to SARS-CoV infection, the ICAM3 Asp143Gly SNP is associated with LDH levels and lower WBC counts in patients with SARS on admission. These findings are in keeping with the role of ICAM3 in T cell activation and the initiation of immune response. Further experiments are required to examine this possibility.

Acknowledgments

We are indebted to Prof. Lap-Chee Tsui for his invaluable advice and support for this project. We thank Ann Yip, Bobo Wong, and N. C. Chan for their assistance in collecting blood samples from the health care workers; Phoebe Ng, Crystal Lai, and Pui Yee Fong (Genome Research Centre) and Kelvin Koo, Vicky Tin, and W. C. Xue (Department of Pathology) for their technical support; and Dr. K. H. Chan (Department of Microbiology, University of Hong Kong) for performing severe acute respiratory syndrome (SARS) serologic testing on health care workers. We also thank Dr. Vivian Wong and Ms. Edwina Shung (Hospital Authority SARS Collaborative Group) for the retrieval of clinical data of patients with SARS from the central database.
