Primary Endovascular Treatment of Post-irradiated Carotid Pseudoaneurysm at the skull base with Pipeline embolization device

ABSTRACT

BACKGROUND: Post-irradiated carotid pseudoaneurysm at the skull base can cause life-threatening blowout syndrome. Conventional treatments include parent vessel occlusion, endovascular coiling or covered stenting. Use of the Pipeline Embolization Device (PED) for pseudoaneurysm exclusion at the skull base is not well described. We report the clinical and angiographic outcome using multiple PED to treat recently ruptured radiation-induced carotid pseudoaneurysms at the skull base.

METHODS: Retrospective review of the clinical and angiographic records of patients who received PED as primary treatment for skull base carotid pseudoaneurysm from 1st April 2011 to 31st March 2013.

RESULTS: 7 patients were treated in the study period including five men and two women, with a mean age of 58 years (range: 47 to 65). Primary treatment with the PED alone, with adjunct coil embolization in 2 patients, achieved immediate hemostasis in all patients, with no pseudoaneurysm rebleeding after a mean follow-up of 15.3 months (range 4-24 months). One patient suffered from peri-procedural cerebral infarction. Delayed ICA occlusion secondary to in-stent thrombosis occurred in 3 patients, 1 of which had lacunar infarct and 2 remained asymptomatic.

CONCLUSION: Endovascular treatment with the PED was effective in excluding skull base post-irradiated carotid pseudoaneurysms and preventing recurrent blowout. However the risk of ischemic complications in this group of patients was high and our experience did not support the use of flow diverters as a first line treatment for this condition.
RUNNING TITLE: Flow diverter for radiation-induced ICA aneurysms at the skull base

PVO, parent artery occlusion (PVO)

PED, pipeline embolization device
INTRODUCTION

Radiotherapy is an effective treatment for head and neck cancers but it may also cause long-term damages to the carotid arteries, resulting in arterial stenosis, occlusion or the formation of pseudoaneurysms.(1) Post-irradiated carotid pseudoaneurysms after radiotherapy for nasopharyngeal cancer typically occur at the petrous and laceral carotid artery, and may present with life-threatening epistaxis due to carotid blowout syndrome (CBS).(2) Recognized treatments for these lesions include parent artery occlusion (PVO) with or without revascularization, endovascular coil embolization, and covered stenting.(3, 4) The introduction of endovascular flow-diverters provides another potential treatment option. The pipeline embolization device (PED) is one of these flow-diverters with 30-35% surface coverage, designed to achieve curative reconstruction of intracranial arteries that harbor aneurysms with challenging morphologies.(5, 6) Outcome in the treatment of non-ruptured intracranial aneurysms was satisfactory.(7-10) However, its efficacy for ruptured pseudoaneurysm, in particular that with an extradural location at the skull base is unclear. We present our experience with the PED in the treatment of patients with ruptured post-irradiated ICA pseudoaneurysms at the skull base.

PATIENTS AND METHODS

Patients

This is a retrospective study of prospectively collected data of all-inclusive patients treated with the PED for radiation-induced extracranial ICA pseudoaneurysms at our institution from April 2011 to March 2013. All patients had history of nasopharyngeal carcinoma primarily treated with prior external radiotherapy involving the skull base, and had developed ICA pseudoaneurysms within the irradiated fields at the skull base. All presented with severe epistaxis due to aneurysm rupture. Initial hemostasis was achieved by means of nasal packing, followed by diagnostic digital subtraction angiography (DSA) and PED reconstruction on an emergency basis within 24 hours.
Procedure and Follow-up

Immediately before PED placement, patients were given 300mg of clopidogrel and 300 mg of aspirin. Clopidogrel (75mg daily) was maintained for at least one week and aspirin (80mg daily) was given for six months after surgery. Low molecular weight heparin was given at 1mg/kg every 12 hours and was maintained for 24 hours after surgery. Intravenous prophylactic antibiotics (amoxicillin-clavulanate 1.2g and metronidazole 500mg) were given on induction of general anesthesia, and maintained for one week post-operatively.

The PED (ev3 Inc, Plymouth, MN, USA) was deployed in the standard manner using transfemoral arterial approach. Additional PEDs were placed telescopically with the overlapping segment covering the entire aneurysm neck for double coverage if there was inadequate contrast stasis in the aneurysm sac. (Figure 3b) Coils were deployed prior to placement of PED when there was ongoing contrast extravasation or the aneurysm sac was large to facilitate hemostasis and thrombosis of pseudoaneurysm. (Figure 2b) A check DSA was performed to ensure that the entire aneurysm neck was covered, and to exclude acute in-stent thrombosis, distal embolism and contrast extravasation through the aneurysm.

Outcome assessment

We assessed the efficacy of immediate and mid-term hemostasis, and the occurrence of peri-procedural complications including ischemic and hemorrhagic neurological events. Follow-up DSA or computer tomography (CT) angiograms were performed to assess aneurysm obliteration, delayed in-stent stenosis and device migration. Patients’ neurologic outcomes were assessed using the modified Rankin’s Score.

RESULTS

Patient characteristics
There were seven patients, including five men and two women, with a mean age of 58 years (range: 47-65). Their clinical features, aneurysm characteristics, and treatment outcomes were summarized in Table 1. Four patients’ primary malignant diseases were in remission; three suffered from recurrent cancers at the time of presentation. The pseudoaneurysms occurred in the petrous and laceral portions of the ICA in five and two patients, respectively. The median aneurysm size was 2.3mm (range: 1.2-12.2mm) All except two patients presented without a prior diagnosis of ICA pseudoaneurysm. Patient 1 had reconstitution of pseudoaneurysm one year after covered stent placement. Patient 2 had undergone treatment for a left-sided pseudoaneurysm at another center 3 months prior to presenting to us with a ruptured right-sided lesion.

Procedural and clinical outcomes

Five patients received two PEDs each, one patient received one device, and another had three devices. Adjuvant coil embolization was used in two patients. The median operation time was 85 minutes (range: 50-236). The median hospital stay was 21 days (range: 4-90). (Table 1) There was no procedure-related mortality. Immediate hemostasis was achieved with DSA confirmed no filling of the pseudoaneurysm in all patients. None experienced recurrent pseudoaneurysm bleeding after a mean clinical follow-up period of 15.3 months (range 4-24 months).

The patient who had a contralateral pseudoaneurysm treated previously (Patient 2) suffered from ischemic cerebral infarctions after PED placement at our center. There was left ICA occlusion, presumably due to previous treatment at another center, as well as 70% right common carotid artery and 50% right proximal ICA stenosis. We performed right ICA angioplasty and stenting for the stenosis prior to PED placement. This patient developed multiple ischemic infarctions afterwards which were likely secondary to endovascular manipulations within a precarious circulation. (Figure 1) There was no other peri-procedural complication.

Follow-up angiographic studies were performed in five patients. Patient 2 as described above declined further investigation, and died of progression of nasopharyngeal cancer 11 months after PED treatment. Another patient (Patient 4) developed pleural effusion secondary to lymphangitis carcinomatosis and carcinoma of the breast and died four months after PED placement. Of the remaining five patients with angiographic follow up, there were no reconstitutions of aneurysm. Two patients (Patients 2 and 7) had asymptomatic in-construct thrombosis at 5 and 7 months respectively. Patient 6 had obliterated aneurysm and patent ICA on CT angiogram at 3 months and remained asymptomatic until at 10 months when a new lacunar infarction at ipsilateral internal capsule developed. There was good neurological recovery. Subsequent DSA showed occluded ipsilateral Right ICA. Their neurologic outcomes were listed in Table 1. Figure 2 and 3 illustrate two patients (Patient 5 and 6) who had complete aneurysm obliterations on initial follow up angiogram.
DISCUSSION

The primary goal of treatment for radiation-induced ICA pseudoaneurysm is the prevention of life-threatening CBS. Since these aneurysms commonly occur at the extradural segments of the ICA located at the skull base, they are rarely amenable to surgical clipping. Endovascular intervention is currently the treatment of choice. PVO in patients with adequate collateral supplies, confirmed on balloon occlusion test (BTO), has been used by many authorities with satisfactory outcome.\(^{(11)}\) However, a subgroup of these patients may still develop severe ischemic complications after PVO which indicates the advantage of preserving the native circulation.\(^{(12)}\) PVO with extracranial-intracranial arterial bypass is another option but the procedure is technically demanding, and sometimes challenging for this group of often debilitated patients.\(^{(13)}\) This cohort of patients typically received repeated radiotherapy for nasopharyngeal cancer and frequently there were bilateral radiation-induced carotid stenosis putting the cerebral circulation at risk. We did not perform routine BTO as we aim to preserve of parent artery with endovascular treatments whenever possible.

Established endovascular therapies for pseudoaneurysm while preserving parent artery include coil embolization and covered-stent exclusion. Coil embolization, for example, can achieve hemostasis effectively.\(^{(4)}\) However, the morphology of some of these lesions (e.g., wide-based or blister-like pseudoaneurysm) may not be suitable for coiling, as were the case in five of our patients. Moreover, these pseudoaneurysms lack a true wall histologically and are commonly surrounded by radionecrotic bone, coil extrusion and rebleeding may occur.\(^{(14, 15)}\) Our center had previously reported the use of self-expandable covered stent-graft in such patients, which has the advantage of achieving immediate reconstruction of the vessel wall.\(^{(15)}\) The initial angiographic outcomes were satisfactory but the presence of tumorous or infected tissues may result in delayed complications such as in-stent thrombosis and infections.\(^{(15-17)}\) Chang et al treated 11 patients with CBS using stent-grafts. Immediate hemostasis was achieved in all patients but five subsequently suffered from rebleeding.\(^{(2)}\) Since 2011, we elect to use flow diverter because of its high metal surface coverage, better maneuverability compared with covered-stents, and because self-expanding covered-stents are no longer available at our locality.
Flow diverters had proven to be an effective treatment for unruptured intracranial aneurysms. (5-9, 18-21) A recent meta-analysis including 1654 intracranial aneurysms found a complete occlusion rate of 76% at 6-months. (22) The PED is known to reduce blood flow within an aneurysm sac to the point of stagnation and thrombosis, and can facilitate neointimal remodeling of the parent artery. Use of the PED for carotid pseudoaneurysm intracranially as well as at the skull base had been reported with mixed results. (23-28) Amenta et al. reported a successful PED treatment for traumatic carotid pseudoaneurysm with a follow up of 4 months. (26) Nerva et al. reported 2 patients with iatrogenic carotid pseudoaneurysm at the cavernous segment after endoscopic transsphenoidal surgery treated with PED and achieved complete aneurysm occlusion. (27) However, early rebleeding after PED treatment in pseudoaneurysms could occur. (24, 28) Our results provide further information on applying PED for post-irradiated carotid pseudoaneurysms located at the skull base. For the 7 patients we treated, all achieved the primary goal of hemostasis and pseudoaneurysm exclusion.

A single PED has 30 to 35% surface area coverage. To secure the pseudoaneurysm and prevent re-rupture, we deliberately used multiple PEDs in 6 of the patients with telescopic placement in an attempt to increase coverage over the aneurysm neck. We also used adjuvant coiling when there was ongoing contrast extravasation or when the aneurysm sac was large. This was necessary in two of our seven patients. This approach was similar to the successful experience by Amenta et al., and Nerva et al., which may suggest the efficacy of multiple flow-diverters in achieving a covered-stent effect to exclude the pseudoaneurysm. (26, 27) Although none of our patients suffered from recurrent hemorrhages after a mean follow-up of over 15 months, the importance of long-term follow-up cannot be over-emphasized. It is also important to emphasize the need for obtaining temporary control of the epistaxis by means of surgical packing prior to PED placement; the latter performed in the presence of active CBS is neither safe nor feasible.

Use of the PED in the context of a recently ruptured intracranial aneurysm causing subarachnoid haemorrhage has also been reported but remains controversial. (29-34) The PED does not always result in an immediate and complete cessation of intrasaccular blood flow. This may lead to rebleeding especially where there is no coil to protect the aneurysm dome. MaAulliffe et al treated 11 patients with recently ruptured intracranial aneurysms. Two patients suffered from
bleeding and the author cautioned against this application.(33) Another concern is the need for
dual antiplatelet agents after PED placement, complicating the risk of rebleeding and
hydrocephalus management.

Despite the reasonable results for preventing rebleeding, our patients demonstrated a higher rate
of ischemic complications than generally reported for the PED. Patient 2 had an occluded left
carotid artery and multifocal stenosis of the right carotid artery due to previous radiation. In order
to secure the pseudoaneurysm, we had to perform angioplasty and negotiate through the proximal
stenosed carotid artery before deploying the PED. He suffered from peri-procedural infarct. In
addition, 3 patients developed delayed stent thrombosis, of which 1 was symptomatic.
Symptomatic infarctions secondary to delayed in-stent thrombosis similar to Patient 6 have been
reported.(6, 35). Patient 6 was put on double anti-platelet agents since PED placement,
clopidogrel was stopped 2 weeks later and aspirin maintained for 6 months. This patient
remained asymptomatic for 4 months after cessation of all anti-platelet therapy, and only
developed lacunar infarct with in-construct thrombosis at 10 months after initial PED placement.

We surmise this worrisome rate of ischemic complications may be due to the inadequate
antiplatelet regimen we used in this particular group of patients, compounded with delayed
endothelialization of irradiated parent arteries as well as use of multiple PEDs. The optimal
duration for antiplatelet treatment after flow diverters is unclear. For elective treatment of
unruptured aneurysms, we routinely prescribe double antiplatelet agents for at least 3 months
followed by aspirin for 6 months in total. However, in the present study, the patients were
constantly at risk of life-threatening bleeding from the pseudoaneurysm, the osteonecrotic
nasopharynx or recurrent nasopharyngeal tumor. We therefore were much more prudent with
antiplatelet agents and only used double antiplatelet agents for the initial 1-4 weeks followed by
aspirin alone subsequently. Although we did not encounter hemorrhagic complications, this over-
cautious antiplatelet regimen led to a high ischemic risk. The high delayed in-stent thrombosis
rate demonstrated in our series highlighted the importance of adequate antiplatelet treatment. In
light of the significant ischemic risk, long term or even life-long antiplatelet agents may be
indicated after PED placement, in particular in irradiated arteries, although the hemorrhagic risk
remains a concern.
CONCLUSION

Radiation-induced ICA pseudoaneurysms at the skull base are challenging conditions for which endovascular intervention is currently the treatment of choice. The present study indicates that the PED as a primary emergency treatment was effective in excluding recently ruptured pseudoaneurysm and preventing rebleeding. However, there was a significant risk of ischemic complications in this group of patients with irradiated arteries. Adequate antiplatelet agents were mandatory although hemorrhagic risk remain a concern. Our results did not support the use of flow diverters as a first line treatment for this condition over coil embolization or covered stent, and it should be used with discretion.
