Abstract:	<p>Bilateral correlated data are often encountered in medical researches such as ophthalmologic (or otolaryngologic) studies, in which each unit contributes information from paired organs to the data analysis, and the measurements from such paired organs are generally highly correlated. Various statistical methods have been developed to tackle intra-class correlation on bilateral correlated data analysis. In practice, it is very important to adjust the effect of confounder on statistical inferences, since either ignoring the intra-class correlation or confounding effect may lead to biased results. In this article, we propose three approaches for testing common risk difference for stratified bilateral correlated data under the assumption of equal correlation. Five confidence intervals (CIs) of common difference of two proportions are derived. The performance of the proposed test methods and CI estimations is evaluated by Monte Carlo simulations. The simulation results show that the score test statistic outperforms other statistics in the sense that the former has robust type I error rates with high powers. The score CI induced from the score test statistic performs satisfactorily in terms of coverage probabilities with reasonable interval widths. A real data set from an otolaryngologic study is used to illustrate the proposed methodologies.</p>

1 Introduction

Paired correlated data are often collected from all participants in medical studies of group comparisons. For instance, in an ophthalmologic study, researchers are interested in the comparison of two treatments. Participants are randomly administrated into one of the two treatment groups. It is of great interest to investigate if or not the two treatments are clinically equivalent. The efficacy of treatment is evaluated by comparing the numbers of cured eyes at the end of the trials of the two treatment groups. The possible outcomes can be summarized in a contingency table (the recorded outcome would be bilateral cured, unilateral cured or none cured). It is noteworthy that the measurements of both eyes from each participant are likely to be correlated.

Under this framework, various test methods for assessing the equality of proportions and various confidence interval (CI) construction approaches for parameters of interest have been developed. Rosner [1] proposed a so-called "constant R model" based on dependency by assuming that the probability of a response at one side given a response at the other side is proportional to the prevalence rate of corresponding group for the ophthalmologic data. Tang et al. [2], Ma et al. [3], Shan and Ma [4], and Liu et al. [5] have developed asymptotic and exact testing methods for this model, which was empirically shown to perform well. However, Dallal [6] pointed out one drawback of Rosner's

1
2
3
4
5
6
7
8 model; i.e., it could lead a poor fit if the characteristic is almost to
9 occur bilaterally with widely varying group-specific prevalence. Later,
10 Donner [7] suggested an alternative model by assuming that all treat-
11 ment groups share an intra-class correlation coefficient (" ρ model").
12 Thompson [8] evaluated this " ρ model" by simulation and confirmed
13 that this model is robust for paired data. Furthermore, various asymp-
14 totic and exact testing methods have been proposed by Tang et al. [9],
15 Pei et al. [10], and Ma and Liu [11]. In addition, CI estimation for
16 risk difference of two proportions based on aforementioned two mod-
17 els has received considerable attentions in statistical literature. For
18 instance, Tang et al. [12] and Pei et al. [13] investigated asymptotic
19 CI construction in two pre-specified models for the difference of pro-
20 portions between two groups. Recently, Yang et al. [14] constructed
21 asymptotic CIs for many-to-one comparisons of proportion differences
22 with multiplicity adjustment.

38 However, one important feature for practical consideration is the
39 stratification factor or confounding effect. Many randomized controlled
40 trials (RCTs) recruit patients to multiple centers or hospitals, rather
41 than to a single center, and we expect that the patients in the same cen-
42 ter tend to have correlated outcomes. It is often necessary to account
43 for the center-effect in the data analysis, since ignoring the stratifica-
44 tion factor will lead to incorrect assumptions in the study, and will
45 result in invalid inference [15] [16][17]. In addition, in some RCTs with

7
8 large number of confounders, some confounders, by chance, could ap-
9
10 pear imbalanced with treatment arms, making it desirable to adjust
11
12 for the stratification factors in the analysis to obtain valid inferences.
13
14 For these reasons, it has been emphasized that extra care should be
15
16 taken in the analysis of the stratified data.
17

18 With the aforementioned models in hand, computational methods
19
20 for testing or constructing CIs on the stratified data analysis for bi-
21
22 lateral binary observations have evolved dramatically in recent years.
23
24 Pei et al. [18] proposed a homogeneity test of proportion ratios for
25
26 stratified bilateral data based on Donner's model. Tang and Qiu [19]
27
28 applied Rosner's model on common difference test of two proportions,
29
30 in which they specified the common difference being zero. Moreover,
31
32 Shen and Ma [20] introduced three alternative testing procedures based
33
34 on maximum likelihood estimates (MLEs) for testing homogeneity of
35
36 difference of two proportions for stratified correlated bilateral data un-
37
38 der a common intra-cluster correlation assumption. Particularly, if we
39
40 fail to reject the null hypothesis that the differences of two proportions
41
42 are equal among strata, the problem of interest may shift to explore
43
44 what is the equivalent value. Therefore, in this article, we develop sev-
45
46 eral procedures for testing equality of difference of two proportions in
47
48 a stratified bilateral design under a common intra-cluster correlation
49
50 model with the condition that the MLEs are derived from the restric-
51
52 tion of equal common difference, and construct asymptotic CIs for that
53

common difference.

The rest of this article is organized as follows. In Section 2, we briefly delineate the data structure. Then the MLEs, three different test procedures and CI estimators are derived in Section 3. Simulation studies are conducted to investigate the performance of the three tests and five CIs in Section 4. A real example from otolaryngologic study is used to illustrate our proposed methods in Section 5. Some concluding remarks and future works are discussed in Section 6.

2 Data Structure

Suppose that our purpose is to test if or not two treatments of some eye disease are clinically equivalent among different age strata in a medical comparative study. The data structure of interest is shown in Table 1. A total of N_j patients are randomly allocated into one of two treatment groups for the j^{th} age stratum ($j = 1, \dots, J$). Let m_{lij} represent the number of patients having l ($l = 0, 1, 2$) eyes with improvement response(s) in the i^{th} ($i = 1, 2$) group from the j^{th} stratum, and $m_{.ij} = \sum_{l=0}^2 m_{lij}$ be the total number of patients in the i^{th} group from the j^{th} stratum. Define $Z_{hijk} = 1$ if there exists an improvement for the h^{th} ($h = 1, 2$) eye of the k^{th} ($k = 1, \dots, m_{.ij}$) patient in the i^{th} group from the j^{th} stratum, and 0 otherwise.

We assume that the probability of improvement at one eye for the

patient in the i^{th} group from the j^{th} stratum is $\Pr(Z_{hijk} = 1) = \pi_{ij}$
 ($0 \leq \pi_{ij} \leq 1$, $h = 1, 2$, $i = 1, 2$). For the " ρ model" (Donner [7]),
 the constant ρ_{ij} ($-1 \leq \rho_{ij} \leq 1$) denotes a measure of within-subject
 correlation. It is easy to show that the improvement probabilities for
 none, one, and both eyes in the i^{th} group from the j^{th} stratum are
 $(1 - \pi_{ij})(1 - \pi_{ij} + \rho_{ij}\pi_{ij})$, $2\pi_{ij}(1 - \rho_{ij})(1 - \pi_{ij})$, and $\pi_{ij}^2 + \rho_{ij}\pi_{ij}(1 - \pi_{ij})$,
 respectively. Note that we assume intra-cluster correlation coefficients
 from two groups are equal within each stratum, whereas they are dif-
 ferent among strata. In what follows, we replace ρ_{ij} with ρ_j .

Table 1: Data structure for the j^{th} ($j = 1, \dots, J$) stratum in a stratified bilateral design

Number of responses (l)	Group (i)		Total
	1	2	
0	m_{01j}	m_{02j}	S_{0j}
1	m_{11j}	m_{12j}	S_{1j}
2	m_{21j}	m_{22j}	S_{2j}
Total	$m_{.1j}$	$m_{.2j}$	N_j

3 Proposed Methods

3.1 Testing Methods

We want to test if the risk differences between two groups among all strata are equal to a common d_0 ; i.e., the considered null hypothesis is $H_0: d_1 = \dots = d_J \triangleq d = d_0$, versus $H_a: d \neq d_0$, where $d_j = \pi_{2j} - \pi_{1j}$. Let $\mathbf{m}_j = \{m_{01j}, m_{11j}, m_{21j}; m_{02j}, m_{12j}, m_{22j}\}$ denote the observed data for the j^{th} stratum as shown in Table 1. Then, the log-likelihood of parameters of interest based on \mathbf{m}_j is

$$l_j(\pi_{1j}, \pi_{2j}, \rho_j | \mathbf{m}_j) = \sum_{i=1}^2 \{m_{0ij} \log[(1 - \pi_{ij})(\rho_j \pi_{ij} - \pi_{ij} + 1)] + m_{1ij} \log[2\pi_{ij}(1 - \rho_j)(1 - \pi_{ij})] + m_{2ij} \log[\pi_{ij}^2 + \rho_j \pi_{ij}(1 - \pi_{ij})]\} + \text{constant},$$

so that the overall log-likelihood function is

$$l = \sum_{j=1}^J l_j.$$

(a) Global MLEs

We first derive the MLEs of parameters from a global setup. Setting the partial differentiation of l_j with respect to π_{ij} 's and ρ_j 's equal to zero yields the MLEs of the parameters, denoted by $\tilde{\pi}_{ij}$ and $\tilde{\rho}_j$,

respectively, where

$$\begin{aligned} \frac{\partial l}{\partial \pi_{ij}} &= \frac{(2\pi_{ij} - 1) m_{1ij}}{\pi_{ij} (\pi_{ij} - 1)} + \frac{m_{2ij} (\rho_j + 2\pi_{ij} - 2\rho_j \pi_{ij})}{\pi_{ij} (\rho_j + \pi_{ij} - \rho_j \pi_{ij})} \\ &\quad - \frac{m_{0i} (\rho_j + 2\pi_{ij} - 2\rho_j \pi_{ij} - 2)}{(\pi_{ij} - 1) (\rho_j \pi_{ij} - \pi_{ij} + 1)}, \quad i = 1, 2, \\ \frac{\partial l}{\partial \rho_j} &= \sum_{i=1}^2 \left[\frac{m_{1ij}}{(\rho_j - 1)} - \frac{(\pi_{ij} - 1) m_{2ij}}{(\rho_j + \pi_{ij} - \rho_j \pi_{ij})} + \frac{\pi_{ij} m_{0ij}}{(\rho_j \pi_{ij} - \pi_{ij} + 1)} \right]. \end{aligned}$$

There are no closed form solutions for $\tilde{\pi}_{ij}$ and $\tilde{\rho}_j$. Therefore, classical techniques such as the Newton–Raphson or the Fisher scoring algorithms are usually recommended in these cases. However, for the current problem with high-dimensional parameters there are computational challenges. Therefore, these MLEs can be computed by repeating the following steps derived by Ma and Liu [11] and Shen and Ma [20]. We can simplify the first equation into a cubic equation,

$$\begin{aligned} &(4\rho_j - 2\rho_j^2 - 2)m_{ij}\pi_{ij}^3 + [3\rho_j^2 m_{ij} - \rho_j(5m_{0ij} + 6m_{1ij} + 7m_{2ij}) + 2m_{0ij} + 3m_{1ij} + 4m_{2ij}]\pi_{ij}^2 \\ &+ [(4\rho_j - \rho_j^2)m_{ij} - 2\rho_j m_{0ij} - m_{1ij} - 2m_{2ij}]\pi_{ij} - \rho_j(m_{1ij} + m_{2ij}) = 0, \end{aligned}$$

and obtain the MLE of π_{ij} by solving the real root of it. Then ρ_j can be updated by the Fisher scoring algorithm. The $(t+1)^{th}$ approximate of ρ_j is

$$\rho_j^{(t+1)} = \rho_j^{(t)} - \left[\frac{\partial^2 l(\pi_{1j}^{(t)}, \pi_{2j}^{(t)}; \rho_j^{(t)})}{\partial \rho_j^2} \right]^{-1} \frac{\partial l(\pi_{1j}^{(t)}, \pi_{2j}^{(t)}; \rho_j^{(t)})}{\partial \rho_j},$$

where $j = 1, \dots, J$. The $(t + 1)^{th}$ update of π_{ij} can be assessed by the solution of the cubic equation by replacing ρ_j with $\rho_j^{(t+1)}$. Repeat the above steps until convergence. The expression of $\frac{\partial^2 l}{\partial \rho_j^2}$ is given in the Appendix A.1.

(b) Unconstrained MLEs

We now consider the unconstrained MLEs. Based on the alternative hypothesis, we can see that π_{2j} can be expressed as $\pi_{1j} + d$, where $d \neq d_0$. Thus, the parameters here only involve ρ_j , π_{1j} , and a common given d . Differentiating l_j with respect to (ρ_j, π_{1j}, d) and setting them equal to zero yield the MLEs of the parameters $\hat{\rho}_j$, $\hat{\pi}_{1j}$ and \hat{d} .

Closed-form solutions of $(\hat{\rho}_j, \hat{\pi}_{1j}, \hat{d})$ are not available. Similarly, we can employ the two-step approach of Shen and Ma [20] by updating the common d via the Newton–Raphson algorithm. Then, we apply the Fisher scoring algorithm to estimate π_{1j} and ρ_j with a given d from each stratum. The iteration procedure is described as follows:

1. The initial values of d and π_{1j} are set as $d^{(0)} = \frac{1}{J} \sum_{j=1}^J \tilde{d}_j$, $\pi_{1j}^{(0)} = \frac{1}{J} \sum_{j=1}^J \tilde{\pi}_{1j}$, $\rho_j^{(0)} = \frac{1}{J} \sum_{j=1}^J \tilde{\rho}_j$, where $\tilde{\pi}_{1j}$ and $\tilde{\rho}_j$ are global MLEs, and $\tilde{d}_j \triangleq \tilde{\pi}_{2j} - \tilde{\pi}_{1j}$.
2. Update

$$d^{(t+1)} = d^{(t)} - \frac{1}{I_1^{(t)}} \times V^{(t)},$$

$$\text{where } V^{(t)} = \sum_{j=1}^J \frac{\partial l_j(\pi_{1j}^{(t)}, \rho_j^{(t)}, d^{(t)})}{\partial d} \text{ and } I_1^{(t)} = \sum_{j=1}^J \frac{\partial^2 l_j(\pi_{1j}^{(t)}, \rho_j^{(t)}, d^{(t)})}{\partial d^2}.$$

See Appendix A.2 for the more details.

3. Update

$$\begin{bmatrix} \pi_{1j}^{(t+1)} \\ \rho_j^{(t+1)} \end{bmatrix} = \begin{bmatrix} \pi_{1j}^{(t)} \\ \rho_j^{(t)} \end{bmatrix} + I_2^{-1}(\pi_{1j}^{(t)}, \rho_j^{(t)}, d^{(t)}) \begin{bmatrix} \frac{\partial l(\pi_{1j}^{(t)}, \rho_j^{(t)}, d^{(t)})}{\partial \pi_{1j}} \\ \frac{\partial l(\pi_{1j}^{(t)}, \rho_j^{(t)}, d^{(t)})}{\partial \rho_j} \end{bmatrix}, j = 1, \dots, J,$$

where I_2 is the Fisher information matrix for π_{1j} and ρ_j . The formula of I_2 and the corresponding differential equations with respect to d are given in Appendix A.2.

4. Repeating Steps 2–3 until convergence.

We denote the MLEs of parameters under the alternative hypothesis by $(\hat{\pi}_{11}, \dots, \hat{\pi}_{1J}; \hat{\rho}_1, \dots, \hat{\rho}_J; \hat{d})$.

(c) Constrained MLEs

Finally, we investigate the constrained MLEs. Under the null hypothesis $H_0: d_1 = \dots = d_J \triangleq d = d_0$, the parameter π_{2j} can be expressed as $\pi_{1j} + d_0$, where d_0 is a known value. The parameters here only involve ρ_j and π_{1j} . Therefore, we can simply utilize the Step 3 in solving unconstrained MLEs with a given d_0 . Let $(\hat{\pi}_{11H_0}, \dots, \hat{\pi}_{1JH_0}; \hat{\rho}_{1H_0}, \dots, \hat{\rho}_{JH_0})$ be the constrained MLEs of the nuisance parameters $(\pi_{11}, \dots, \pi_{1J}; \rho_1, \dots, \rho_J)$. With all MLEs obtained, we consider the following test procedures and CI estimation approaches.

3.1.1 Likelihood ratio test (T_L)

The likelihood ratio test (LRT) statistic is given by

$$T_L = 2[l(\hat{\pi}_{11}, \hat{\pi}_{21}, \dots, \hat{\pi}_{1J}, \hat{\pi}_{2J}; \hat{\rho}_1, \dots, \hat{\rho}_J) - l(\hat{\pi}_{11H_0}, \hat{\pi}_{11H_0} + d_0, \dots, \hat{\pi}_{1JH_0}, \hat{\pi}_{1JH_0} + d_0; \hat{\rho}_{1H_0}, \dots, \hat{\rho}_{JH_0})],$$

which asymptotically follows a chi-square distribution with one degree of freedom under the null hypothesis.

3.1.2 Wald-type test (T_W)

First, we rewrite the null hypothesis as $H_0: d_1 = \dots = d_J \triangleq d = d_0$ versus $H_a: d \neq d_0$, where $d_j = \pi_{2j} - \pi_{1j}$. Let $\beta = (d, \pi_{11}, \rho_1, \dots, \pi_{1J}, \rho_J)^T$, the corresponding unconstrained MLE is $\hat{\beta} = (\hat{d}, \hat{\pi}_{11}, \hat{\rho}_1, \dots, \hat{\pi}_{1J}, \hat{\rho}_J)^T$. Then, the MLE of d is $\hat{d} = K \times \hat{\beta}$, where $K = (1, 0, \dots, 0)_{1 \times (2J+1)}$ is a row vector. The Wald-type test statistic is

$$T_W = \frac{(\hat{d} - d_0)^2}{\text{Var}(\hat{d})} = \frac{(\hat{d} - d_0)^2}{K \text{Var}(\hat{\beta}) K^T}.$$

Based on asymptotic normality of the MLEs, one can show that $\text{Var}(\hat{\beta}) = \hat{I}_n^{-1}$, where I_n^{-1} is the inverse of the Fisher information matrix for β , and \hat{I}_n^{-1} is the MLE of I_n^{-1} . Therefore, we can rewrite the Wald-type statistic as

$$T_W = \frac{(\hat{d} - d_0)^2}{\hat{I}_n^{-1}(1, 1)},$$

where $I_n^{-1}(1, 1)$ stands for the $(1, 1)^{th}$ entry of I_n^{-1} . Under the null hypothesis, T_W is asymptotically distributed as a chi-square distribution with one degree of freedom.

3.1.3 Score test (T_{SC})

The score test statistic T_{SC} utilizes the MLEs of parameters under H_0 . The score is a row vector: $\mathbf{U}(d, \boldsymbol{\pi}, \boldsymbol{\rho}) = \left(\frac{\partial l}{\partial d}, \frac{\partial l}{\partial \pi_{11}}, \frac{\partial l}{\partial \rho_1}, \dots, \frac{\partial l}{\partial \pi_{1J}}, \frac{\partial l}{\partial \rho_J} \right)$, where $\boldsymbol{\pi} = (\pi_{11}, \pi_{12}, \dots, \pi_{1J})$ and $\boldsymbol{\rho} = (\rho_1, \rho_2, \dots, \rho_J)$. Then T_{SC} for testing the equality of proportion difference is expressed as

$$T_{SC} = \mathbf{U} \mathbf{I}^{-1} \mathbf{U}^T |_{H_0},$$

where \mathbf{I} is the information matrix for $\boldsymbol{\beta} = (d, \pi_{11}, \rho_1, \dots, \pi_{1J}, \rho_J)^T$. Here, d is the parameter of interest, while π_{1j} and ρ_j are nuisance parameters. Therefore, the score function is $\mathbf{U} = \left(\frac{\partial l}{\partial d}, 0, 0, \dots, 0 \right) |_{d=d_0}$. The test statistics can be simplified as

$$T_{SC} = \left(\sum_{j=1}^J \frac{\partial l_j}{\partial d} \right)^2 I_n^{-1}(1, 1),$$

where $I_n^{-1}(1, 1)$ represents the $(1, 1)^{th}$ entry of I_n^{-1} , and the formula of $\frac{\partial l_j}{\partial d}$ is given in Appendix. Under the null hypothesis, T_{SC} is asymptotically distributed as a chi-square distribution with one degree of freedom.

3.2 Confidence Interval Estimation

3.2.1 Global Wald-type CI and alternative Wald-type CI (GW, AW)

Recall that we have derived the MLE of $\beta = (\pi_{11}, \pi_{21}, \rho_1, \dots, \pi_{1J}, \pi_{2J}, \rho_J)^T$ from the global setup and alternative hypothesis, and denoted them by $\tilde{\beta} = (\tilde{\pi}_{11}, \tilde{\pi}_{21}, \tilde{\rho}_1, \dots, \tilde{\pi}_{1J}, \tilde{\pi}_{2J}, \tilde{\rho}_J)^T$ and $\hat{\beta} = (\hat{\pi}_{11}, \hat{\pi}_{21}, \hat{\rho}_1, \dots, \hat{\pi}_{1J}, \hat{\pi}_{2J}, \hat{\rho}_J)^T$, respectively, where $\tilde{\pi}_{2j} = \tilde{\pi}_{1j} + \tilde{d}$, and $\hat{\pi}_{2j} = \hat{\pi}_{1j} + \hat{d}$, for $j = 1, \dots, J$.

Intuitively, we consider that there exist weights $\{w_j\}$ assigned to each stratum satisfying $d = \sum_{j=1}^J w_j d_j$ and $\sum_{j=1}^J w_j = 1$, where $j = 1, \dots, J$. The choice of weights is not trivial. Here, we suggest two ways. (1) Uniformly weights: $w_j = \frac{1}{J}$. (2) Sample size weights: $w_j = \frac{N_j}{N}$, where N_j is the sample size of the j^{th} stratum and $N = \sum_{j=1}^J N_j$ is the total number of patients.

We apply the algorithm to construct CI for d_0 by a row vector $\mathbf{W} = (w_1, \dots, w_J)$ and a constant matrix,

$$\mathbf{K} = \begin{pmatrix} -1 & 1 & 0 & \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & -1 & 1 & 0 & \dots & \dots & \dots & \dots & \dots \\ \vdots & & & \ddots & \ddots & \ddots & & & & & \vdots \\ \vdots & & & & \ddots & \ddots & \ddots & & & & \vdots \\ \vdots & & & & & \ddots & \ddots & \ddots & & & \vdots \\ 0 & \dots & \dots & \dots & \dots & \dots & \dots & -1 & 1 & 0 & \dots \end{pmatrix}_{J \times 3J}$$

Thus, the MLEs of d from both setups can be obtained by a simple linear transformation:

$$\tilde{d} = \sum_{j=1}^J w_j \tilde{d}_j = \mathbf{C} \tilde{\boldsymbol{\beta}},$$

and

$$\hat{d} = \sum_{j=1}^J w_j \hat{d}_j = \mathbf{C} \hat{\boldsymbol{\beta}},$$

where $\mathbf{C} = \mathbf{W} \cdot \mathbf{K} = (-w_1, w_1, 0, -w_2, w_2, 0, \dots, -w_j, w_j, 0)_{1 \times 3J}$.

It is straightforward to show that $\frac{(\tilde{d}-d_0)}{\sqrt{\text{Var}(\tilde{d})}}$ and $\frac{(\hat{d}-d_0)}{\sqrt{\text{Var}(\hat{d})}}$ are asymptotically distributed as the standard normal distribution as the sample size is large. In addition, according to the asymptotic normality of the MLE, we can express the variance of the d in terms of \mathbf{C} and the information matrix of $\boldsymbol{\beta}$; that is $\text{Var}(\mathbf{C}\boldsymbol{\beta}) = \mathbf{C}I^{-1}\mathbf{C}^T$, where I is the information matrix of $\boldsymbol{\beta}$.

Therefore, the $100(1-\alpha)\%$ CI of d_0 based on above two setups are respectively, given by

$$\left[\max\left(-1, \tilde{d} - Z_{1-\alpha/2} \sqrt{\mathbf{C}\tilde{I}^{-1}\mathbf{C}^T}\right), \min\left(1, \tilde{d} + Z_{1-\alpha/2} \sqrt{\mathbf{C}\tilde{I}^{-1}\mathbf{C}^T}\right) \right],$$

and

$$\left[\max\left(-1, \hat{d} - Z_{1-\alpha/2} \sqrt{\mathbf{C}\hat{I}^{-1}\mathbf{C}^T}\right), \min\left(1, \hat{d} + Z_{1-\alpha/2} \sqrt{\mathbf{C}\hat{I}^{-1}\mathbf{C}^T}\right) \right],$$

where $Z_{1-\alpha/2}$ is the $(1 - \alpha/2)$ quantile of the standard normal distribution.

3.2.2 Complete Wald-type CI (W)

As aforementioned Wald-type test in Section 3.1.2, $\frac{(\hat{d}-d_0)}{\sqrt{\text{Var}(\hat{d})}}$ asymptotically follows the standard normal distribution, where $\text{Var}(\hat{d}) = \hat{I}_n^{-1}(1, 1)$, $I_n^{-1}(1, 1)$ is the $(1, 1)^{th}$ element of the inverse of information matrix under H_a . Therefore, the $100(1 - \alpha)\%$ CI for $d_0 \in [-1, 1]$ is defined as

$$\left[\max \left(-1, \hat{d} - Z_{1-\alpha/2} \sqrt{\hat{I}_n^{-1}(1, 1)} \right), \min \left(1, \hat{d} + Z_{1-\alpha/2} \sqrt{\hat{I}_n^{-1}(1, 1)} \right) \right].$$

3.2.3 Profile likelihood CI (PL)

With the pre-specified common test in Section 3.1.1, we intuitively propose an approach to assess the CI estimation from χ^2 distribution by inverting the LRT of $H_0: d_1 = \dots = d_J \triangleq d = d_0$ versus $H_a: d \neq d_0$, where $d_j = \pi_{2j} - \pi_{1j}$. Since the LRT statistic follows a chi-square distribution with one degree of freedom under the null hypothesis, the $100(1 - \alpha)\%$ CI satisfies

$$2[l(\hat{d}_0, \hat{\pi}_{1j}, \hat{\rho}_j) - l(d_0, \hat{\pi}_{1jH_0}, \hat{\rho}_{jH_0})] \leq \chi_{1,1-\alpha}^2,$$

where $\chi_{1,1-\alpha}^2$ is the $1 - \alpha$ quantile of the chi-square distribution with one degree of freedom.

The bisection method can be used to obtain the lower/upper limits of above inequality (Yang, Tian, Liu, and Ma [14]). To assess the upper limit, the iteration procedure can be performed as follows.

1. Start with the initial values $\hat{d}^{(0)} = \hat{d}$, stepsize=0.1, and flag=1, where \hat{d} is unconstrained MLE of d .
2. Update $\hat{d}^{(t+1)} = \hat{d}^{(t)} + \text{stepsize} \times \text{flag}$, and compute constrained MLE for $(\pi_{11}, \dots, \pi_{1J}; \rho_1, \dots, \rho_J)^{(t+1)}$. Then, the log-likelihood function can be calculated according to the constrained MLEs and the data, denoted by $\hat{l}^{(t+1)}$.
3. Evaluate the aforementioned requirement of CI. If the condition of $2 \times \text{flag} \times [l(\hat{d}, \hat{\pi}_{11}, \dots, \hat{\pi}_{1J}; \hat{\rho}_1, \dots, \hat{\rho}_J) - \hat{l}^{(t+1)}] \leq \text{flag} \times \chi_{1,1-\alpha}^2$ is satisfied, return to Step 2. Otherwise, we change the direction to search the bound. That is, set $\text{flag} = -\text{flag}$, step size = $0.1 \times$ step size, then return to Step 2.
4. Repeating the iteration process 2-3 until convergence (that is, the stepsize is sufficiently small, say, 10^{-5}).

Similarly, we repeat the iteration procedure with $\text{flag} = -1$ to assess the lower limit of CI.

3.2.4 Score CI (SC)

Since the score test statistic also follows a chi-square distribution with one degree of freedom under the null hypothesis, one can assess the $100(1 - \alpha)\%$ CI by including all $-1 \leq d_0 \leq 1$ which satisfies

$$T_{SC} \leq \chi_{1,1-\alpha}^2,$$

where T_{SC} is the test statistics given in Section 3.1.3. Similarly, the bisection method is used to search the lower and upper limits.

4 Simulation Studies

4.1 Common risk difference test

We now investigate the performance of the proposed three statistics for testing the equality of risk differences. We first evaluate the behavior of the type I error rate under various parameter settings, where $m = m_{.11} = m_{.21} = \dots = m_{.1J} = m_{.2J} = 25, 50$ or 100 in $J=2, 4$ or 8 strata, respectively. The parameter setups are displayed in Table 2, and we consider three values for common differences across strata under H_0 : $d_0 = 0, 0.1$ or 0.2 , with various sets of parameters under different sample sizes. For each setup, 10,000 samples are randomly generated under null hypothesis and empirical type I error rates are computed by dividing the number of times of rejecting the null hypothesis with

10,000. All tests are conducted at 5% significance level.

Table 2: Parameter setups for computing empirical type I error rates and powers

Cases		Number of strata		
		$J = 2$	$J = 4$	$J = 8$
ρ	I	(0.2, 0.4)	(0.2, 0.4, 0.2, 0.4)	(0.2, 0.4, 0.2, 0.4, 0.2, 0.4, 0.2, 0.4)
	II	(0.3, 0.3)	(0.3, 0.3, 0.3, 0.3)	(0.3, 0.3, 0.3, 0.3, 0.3, 0.3, 0.3, 0.3)
	III	(0.3, 0.5)	(0.3, 0.5, 0.3, 0.5)	(0.3, 0.5, 0.3, 0.5, 0.3, 0.5, 0.3, 0.5)
	IV	(0.6, 0.6)	(0.6, 0.6, 0.6, 0.6)	(0.6, 0.6, 0.6, 0.6, 0.6, 0.6, 0.6, 0.6)
π_1	a	(0.2, 0.4)	(0.2, 0.4, 0.2, 0.4)	(0.2, 0.4, 0.2, 0.4, 0.2, 0.4, 0.2, 0.4)
	b	(0.3, 0.3)	(0.3, 0.3, 0.3, 0.3)	(0.3, 0.3, 0.3, 0.3, 0.3, 0.3, 0.3, 0.3)
	c	(0.4, 0.4)	(0.4, 0.4, 0.4, 0.4)	(0.4, 0.4, 0.4, 0.4, 0.4, 0.4, 0.4, 0.4)

Following Tang et al. [21], at 0.05 nominal level, we define a test is liberal if the empirical type I error is greater than 0.06, conservative if the type I error is less than 0.04, and otherwise robust. The results (Tables 3–5) show that the score test and the LRT are robust in terms of satisfactory type I error for all scenarios. The Wald-type test mostly works well at larger sample size ($m = 50$ or 100), but becomes inflated at smaller sample scenario ($m = 25$) and lower strata scenario ($J = 2$). Additionally, a set of boxplots (Figure 1) showed the distribution for the empirical type I error rates for all tests when we have balanced data for $J=2, 4$ or 8 , respectively. We can observe that the score test behaves satisfactorily, in the sense that its type I error rate is close to the pre-determined nominal level 0.05 for any configuration. The LRT is inflated, while the Wald-type test is even worse. However, as the sample size increases, both the LRT and the Wald-type test perform

1
2
3
4
5
6
7
8 better.

9
10 Next, we investigate the performance of power for proposed test
11 statistics under various parameters settings. To be specific, we consider
12 the same sample sizes and parameter setups as we did for computing
13 empirical type I error. Tables 6–8 report empirical power associated
14 with three proposed tests for various configurations. Since powers pro-
15 duced by three tests under different d_0 perform similarly, results from
16 one case ($d_0 = 0.1$) are presented. We can also observe that, under
17 the same parameter settings, the powers of different test statistics are
18 very close. The Wald-type test tends to produce larger power than
19 other two tests. Powers produced by all three tests increase when the
20 difference between the true d (denoted by d_a) and d_0 increases. Powers
21 increase when the number of strata J goes larger. Overall, the score
22 test is highly recommended, since it is satisfactory on type I error
23 control and has a good performance on power.

39 4.2 Confidence interval estimation

40
41 In this subsection, we compare the proposed five CI estimators with one
42 existing CI estimator from balanced to unbalanced designs in terms of
43 empirical coverage probability (ECP) and mean interval width (MIW).
44 The ECP is defined as the proportion of events that d_0 falls within the
45 constructed CI, and the MIW is calculated by dividing the sum of all
46 widths with 10,000. Following Yang et al. [14], CI can be constructed

8 with pooling data, where the objective of interest is only the treatment
9 group variable. We only present the result of this marginal CI for score
10 method (MSC). In addition, we construct global Wald-type CIs with
11 uniformly weighted adjustment and sample size weighted adjustment,
12 respectively, namely GW1 and GW2, and also construct alternative
13 Wald-type CIs with uniformly weighted adjustment and sample size
14 weighted adjustment, respectively, namely AW1 and AW2. The pa-
15 rameter setup is given in Table 9. Under each configuration, 10,000
16 Monte Carlo samples are generated, and 95% CI is constructed for
17 each replicate. Results are shown in Tables 10–12. Accordingly, we
18 display a set of boxplots to investigate the distribution of ECPs and
19 MIWs for unbalanced cases (Figure 2). Generally, CIs based on strata
20 assumption outperform CIs based on marginal model since the ECPs
21 of those are closer than pre-determined CI. Among those CIs consider-
22 ing strata assumption, score CIs behave satisfactorily, since the ECPs
23 are the closest to the pre-determined confidence level, and MIWs are
24 reasonable short. It is hence recommended. Likelihood ratio statistic
25 produces CIs with shorter MIWs, but it yields deflated ECPs. Wald-
26 type statistic (without weighted correction) can hardly well control its
27 ECP, but produces the shortest MIW. The CIs based on global Wald
28 statistics with weighted correction (GW1 and GW2) and alternative
29 Wald statistics with weighted correction (AW1 and AW2) appear to
30 perform poorly, especially when the number of strata is large ($J = 4$

or $J = 8$). Therefore, CI produced from the score statistic is strongly recommended in practice.

π_1	a	(0.3, 0.5)	(0.3, 0.5, 0.3, 0.5)	(0.3, 0.5, 0.3, 0.5, 0.3, 0.5, 0.3, 0.5)
	b	(0.4, 0.4)	(0.4, 0.4, 0.4, 0.4)	(0.4, 0.4, 0.4, 0.4, 0.4, 0.4, 0.4, 0.4)

5 A Real Example

We analyze a real example in this section to further evaluate the performance of aforementioned methods. Mandel et al [22] reported a data set from a double-blind randomized clinical trial to compare cefaclor and amoxicillin for the treatment of otitis media with effusion (OME) in children with bilateral tympanocentesis. Children with OME were randomized into two groups, and children in each group received a 14-day course with one of two antibiotics (amoxicillin or cefaclor). After the treatment, the number of cured ears for each child was recorded. We first classify the children as three age groups, and then discuss

whether the cured rates between the amoxicillin or cefaclor among age are clinically equivalent. We summarize the observed data in Table 13.

Table 13: Number of children whose ears have improvement across different strata. (Group 1: Cefaclor; Group 2: Amoxicillin)

Age groups	Age < 2yrs		Age 2–5 yrs		Age ≥ 6yrs	
	1	2	1	2	1	2
0	8	11	6	3	0	1
1	2	2	6	1	1	0
2	8	2	10	5	3	6
Total	18	15	22	9	4	7

Based on the data given above, all MLEs of parameters are reported in Table 14. First, we consider testing homogeneity proposed by Shen and Ma [20]. For the homogeneity test, the null hypothesis is $H_0: d_1 = d_2 = d_3 \triangleq d$ versus H_a : some of d_j s are not equal for $j \in \{1, 2, 3\}$, values of the three test statistics are $T_L = 2.83$, $T_W = 2.93$, $T_{SC} = 2.76$ and the corresponding p -values are 0.24, 0.23, 0.25, respectively. We note that all p -values are greater than the nominal level $\alpha = 0.05$, indicating that the differences of cured ears between two groups are not correlated to the age effect. Next, we consider a common test to check whether or not $d = 0$. The corresponding values of common test statistics and their p -values are presented in Table 15. In addition, CI

estimators are given in Table 16. These results imply that there are no significant differences between two groups among age strata (i.e., the cured rates between the amoxicillin and cefaclor among age are clinically equivalent).

Table 14: MLEs of parameters based on observed data

Age groups	Global MLEs			Unconstrained MLEs			Constrained MLEs		
	$\tilde{\rho}$	$\tilde{\pi}_1$	\tilde{d}	$\hat{\rho}$	$\hat{\pi}_1$	\hat{d}	$\hat{\rho}_{H_0}$	$\hat{\pi}_{1H_0}$	\hat{d}_{H_0}
Age < 2yrs	0.7112	0.5000	-0.2904	0.7282	0.4017	-0.0945	0.7381	0.3636	0
Age 2-5 yrs	0.5307	0.5881	0.0323	0.5330	0.6205	-	0.5308	0.5968	-

6 Conclusions

In this article, we first consider test for common risk difference of two proportions on stratified bilateral correlated data. Three MLE-based test procedures (LRT, Wald-type test and score test) are investigated. Classical algorithms, such as the Fisher scoring and the Newton–Raphson methods are usually criticized for computational difficulty in high-dimensional cases. We derived the two-step approaches for obtaining the unconstrained and constrained MLEs, which are very efficient. Then, we proposed five CIs of common difference of

1
2
3
4
5
6
7
8 two proportions on stratified bilateral correlated data, which include
9
10 two weight-adjusted approaches (global Wald-type CI and alternative
11
12 Wald-type CI) and three test-based approaches.
13

14 Simulation studies show that (i) statistics derived from the score
15
16 test behave satisfactorily in the sense that it has robust type I error,
17
18 and reasonable power regardless of number of strata, sample size or
19
20 parameter configurations. The Wald-type test and LRT yield inflated
21
22 type I error when sample size is relatively small. (ii) CI estimation
23
24 derived from the score test performs well in the sense that its ECP
25
26 is very close to pre-determined confidence level and MIW is short.
27
28 As we expected, interval based on marginal model performs worse,
29
30 since ignorance of the strata (confounding) effect may lead to incorrect
31
32 inference. For these reasons, we highly recommend the score test in
33
34 practical use for stratified bilateral-sample designs.
35

36 For correlated data with binomial distributions, there are many
37
38 well-built model-based methods to calculate the MLE iteratively or
39
40 perform statistical analysis, e.g. "GENMOD" and "GLIMMIX" proce-
41
42 dure in SAS. Ying et al. [23] described and demonstrated appropriate
43
44 linear regression analysis involving both eyes, including mixed effects
45
46 and marginal models under various covariance structures to account
47
48 for inter-eye correlation. These methods also offered the flexibility
49
50 to incorporate covariates in the model. However, those model-based
51
52 methods fail to provide a closed-form solution for either MLEs or test
53

1
2
3
4
5
6
7
8 statistics. The explicit form of solutions improves computational effi-
9
10 ciency, especially when we further develop exact test for small sample
11
12 situation in the future. All proposed methods are asymptotic, and do
13
14 not perform well at relatively small sample sizes. Thus, exact tests are
15
16 necessary to overcome inflated type I error rate as future work. To
17
18 perform exact test, extensive calculations will be required, which make
19
20 it very difficult using model-based methods.
21

22 In this article, we consider the scenario in which we treat strata as
23
24 nominal categories. In clinical trials, one interesting research goal is
25
26 to test if there is a trend among the strata. Some information among
27
28 strata may be ignored when there exists ordinal classification relation-
29
30 ship. We can further develop either asymptotic or exact trend test as
31
32 an interesting future work.

Appendix A Information matrix and formula derivation

A.1 Information matrix for computing global MLEs

The second order differential equations from the j^{th} stratum with respect to π_{ij} ($i = 1, 2$) and ρ_j yield

$$\begin{aligned} \frac{\partial^2 l}{\partial \pi_{ij}^2} &= -\frac{(2\pi_{ij}^2 - 2\pi_{ij} + 1)m_{1ij}}{\pi_{ij}^2 (\pi_{ij} - 1)^2} - \frac{(2\rho_j^2 \pi_{ij}^2 - 2\rho_j^2 \pi_{ij} + \rho_j^2 - 4\rho_j \pi_{ij}^2 + 2\rho_j \pi_{ij} + 2\pi_{ij}^2)m_{2ij}}{\pi_{ij}^2 (\rho_j + \pi_{ij} - \rho_j \pi_{ij})^2} \\ &\quad - \frac{(2\rho_j^2 \pi_{ij}^2 - 2\rho_j^2 \pi_{ij} + \rho_j^2 - 4\rho_j \pi_{ij}^2 + 6\rho_j \pi_{ij} - 2\rho_j + 2\pi_{ij}^2 - 4\pi_{ij} + 2)m_{0ij}}{(\pi_{ij} - 1)^2 (\rho_j \pi_{ij} - \pi_{ij} + 1)^2}, \\ \frac{\partial^2 l}{\partial \pi_{ij} \partial \rho_j} &= \frac{m_{0ij}}{(\rho_j \pi_{ij} - \pi_{ij} + 1)^2} - \frac{m_{2ij}}{(\rho_j \pi_{ij} - \pi_{ij} - \rho_j)^2}, \\ \frac{\partial^2 l}{\partial \pi_{ij} \partial \pi_{kj}} &= 0, \quad i \neq k, \\ \frac{\partial^2 l}{\partial \rho_j^2} &= -\sum_{i=1}^2 \left[\frac{m_{1ij}}{(\rho_j - 1)^2} + \frac{\pi_{ij}^2 m_{0ij}}{(\rho_j \pi_{ij} - \pi_{ij} + 1)^2} + \frac{(\pi_{ij} - 1)^2 m_{2ij}}{(\rho_j + \pi_{ij} - \rho_j \pi_{ij})^2} \right]. \end{aligned}$$

Then from the j^{th} stratum, we have,

$$I_j(\pi_{ij}, \rho_j) = \begin{bmatrix} I_{11(j)} & 0 & I_{13(j)} \\ 0 & I_{22(j)} & I_{23(j)} \\ I_{13(j)} & I_{23(j)} & I_{33(j)} \end{bmatrix},$$

where

$$\begin{aligned}
 I_{ii(j)} &= E \left(-\frac{\partial^2 l}{\partial \pi_{ij}^2} \right) = \frac{m_{.ij} (-4\rho_j^2 \pi_{ij}^2 + 4\rho_j^2 \pi_{ij} - \rho_j^2 + 6\rho_j \pi_{ij}^2 - 6\rho_j \pi_{ij} + 2\rho_j - 2\pi_{ij}^2 + 2\pi_{ij})}{\pi_{ij} (1 - \pi_{ij}) (\rho_j + \pi_{ij} - \rho_j \pi_{ij}) (\rho_j \pi_{ij} - \pi_{ij} + 1)}, \\
 I_{i3(j)} &= E \left(-\frac{\partial^2 l}{\partial \pi_{ij} \partial \rho_j} \right) = \frac{m_{.ij} \rho_j (2\pi_{ij} - 1)}{(\rho_j + \pi_{ij} - \rho_j \pi_{ij}) (\rho_j \pi_{ij} - \pi_{ij} + 1)}, \\
 I_{33(j)} &= E \left(-\frac{\partial^2 l}{\partial \rho_j^2} \right) = \sum_{i=1}^2 \frac{m_{.ij} \pi_{ij} (\rho_j + 1) (1 - \pi_{ij})}{(1 - \rho_j) (\rho_j + \pi_{ij} - \rho_j \pi_{ij}) (\rho_j \pi_{ij} - \pi_{ij} + 1)}.
 \end{aligned}$$

Therefore, the information matrix for J strata has the form

$$I = \begin{bmatrix} I_1(\pi_{i1}, \rho_1) & & & & \\ & I_2(\pi_{i2}, \rho_2) & & & \\ & & \ddots & & \\ & & & & I_J(\pi_{iJ}, \rho_J) \end{bmatrix}_{3J \times 3J},$$

The inverse of the information matrix is

$$I^{-1} = \begin{bmatrix} I_1(\pi_{i1}, \rho_1)^{-1} & & & & \\ & I_2(\pi_{i2}, \rho_2)^{-1} & & & \\ & & \ddots & & \\ & & & & I_J(\pi_{iJ}, \rho_J)^{-1} \end{bmatrix}_{3J \times 3J},$$

where $I_j^{-1}(\pi_{ij}, \rho_j) = \frac{1}{k(j)} \times z(j)$,

$$z(j) = \begin{bmatrix} I_{23(j)}^2 - I_{22(j)} I_{33(j)} & -I_{13(j)} I_{23(j)} & I_{22(j)} I_{13(j)} \\ -I_{13(j)} I_{23(j)} & I_{13(j)}^2 - I_{11(j)} I_{33(j)} & I_{11(j)} I_{23(j)} \\ I_{22(j)} I_{13(j)} & I_{11(j)} I_{23(j)} & -I_{11(j)} I_{22(j)} \end{bmatrix},$$

$$k(j) = I_{22(j)} I_{13(j)}^2 + I_{11(j)} I_{23(j)}^2 - I_{11(j)} I_{22(j)} I_{33(j)}.$$

$$i = 1, 2, j = 1, \dots, J.$$

A.2 Information matrix for computing unconstrained and constrained MLEs

Let $\pi_{2j} = \pi_{1j} + d$, $j = 1, \dots, J$. The first order and second order differential equations from the j^{th} stratum with respect to d are

$$\frac{\partial l_j}{\partial d} = \frac{m_{02j}(2\pi_{2j}\rho_j - \rho_j - 2\pi_{2j} + 2)}{(\pi_{2j}\rho_j - \pi_{2j} + 1)(\pi_{2j} - 1)} + \frac{m_{12j}(2\pi_{2j} - 1)}{\pi_{2j}(\pi_{2j} - 1)} + \frac{m_{22j}(2\pi_{2j}\rho_j - 2\pi_{2j} - \rho_j)}{\pi_{2j}^2\rho_j - \pi_{2j}\rho_j - \pi_{2j}^2},$$

and

$$\begin{aligned} \frac{\partial^2 l_j}{\partial d^2} = & -\frac{m_{02j}(2\pi_{2j}^2\rho_j^2 - 4\pi_{2j}^2\rho_j + 2\pi_{2j}^2 - 2\pi_{2j}\rho_j^2 + 6\pi_{2j}\rho_j - 4\pi_{2j} + \rho_j^2 - 2\rho_j + 2)}{(\pi_{2j}\rho_j - \pi_{2j} + 1)^2(\pi_{2j} - 1)^2} \\ & + \frac{m_{12j}(-2\pi_{2j}^2 + 2\pi_{2j} - 1)}{\pi_{2j}^2(\pi_{2j} - 1)^2} - \frac{m_{22j}(2\pi_{2j}^2\rho_j^2 - 2\pi_{2j}^2\rho_j + 2\pi_{2j}^2 - 2\pi_{2j}\rho_j^2 + 2\pi_{2j}\rho_j + \rho_j^2)}{\pi_{2j}^2(\pi_{2j}\rho_j - \pi_{2j} - \rho_j)^2}. \end{aligned}$$

Moreover, with a given d , information matrix I_2 for π_{1j} and ρ_j is

$$I(\pi_{1j}, \rho_j, d) = \begin{bmatrix} I_{11(j)} & I_{12(j)} \\ I_{12(j)} & I_{22(j)} \end{bmatrix}.$$

Thus, the inverse of the information matrix can be expressed as

$$I^{-1}(\pi_{1j}, \rho_j, d) = \frac{1}{I_{11(j)} \times I_{22(j)} - I_{12(j)}^2} \begin{bmatrix} -I_{22(j)} & I_{12(j)} \\ I_{12(j)} & -I_{11(j)} \end{bmatrix},$$

where

$$\begin{aligned} I_{11(j)} &= E \left(-\frac{\partial^2 l}{\partial \pi_{1j}^2} \right) = \sum_{i=1}^2 \frac{m_{.ij} (-4 \pi_{ij}^2 \rho_j^2 + 6 \pi_{ij}^2 \rho_j - 2 \pi_{ij}^2 + 4 \pi_{ij} \rho_j^2 - 6 \pi_{ij} \rho_j + 2 \pi_{ij} - \rho_j^2 + 2 \rho_j)}{\pi_{ij} (1 - \pi_{ij}) (\pi_{ij} \rho_j - \pi_{ij} + 1) (\pi_{ij} + \rho_j - \pi_{ij} \rho_j)} \\ I_{12(j)} &= E \left(-\frac{\partial^2 l}{\partial \pi_{1j} \partial \rho_j} \right) = \sum_{i=1}^2 \frac{m_{.ij} \rho_j (2 \pi_{ij} - 1)}{(\pi_{ij} \rho_j - \pi_{ij} + 1) (\pi_{ij} + \rho_j - \pi_{ij} \rho_j)}, \\ I_{22(j)} &= E \left(-\frac{\partial^2 l}{\partial \rho_j^2} \right) = \sum_{i=1}^2 m_{.ij} \left(\frac{2 \pi_{ij} (\pi_{ij} - 1)}{\rho_j - 1} - \frac{\pi_{ij}^2 (\pi_{ij} - 1)}{\pi_{ij} \rho_j - \pi_{ij} + 1} + \frac{\pi_{ij} (\pi_{ij} - 1)^2}{\pi_{ij} + \rho_j - \pi_{ij} \rho_j} \right), \end{aligned}$$
