ABSTRACT

Background: To evaluate whether the common risk factors and risk scores (FRAX, QFracture and Garvan) can predict hip fracture in the oldest old (defined as age \geq 80), and to develop an oldest-old specific 10-year hip fracture prediction risk algorithm.

Methods: Subjects aged \geq 80 without history of hip fracture were studied. For the derivation cohort (N=251, mean age=83), participants were enrolled with a median follow-up time of 8.9 years. For the validation cohort (N=599, mean age=85), outpatients were enrolled with a median follow-up of 2.6 years. A 5-factor risk score (the HKOS score) for incident hip fracture was derived and validated, and its predictive accuracy was evaluated and compared with other risk scores.

Results: In the derivation cohort, the C-statistics were 0.65, 0.61, 0.65, 0.76 and 0.78 for FRAX with bone mineral density (BMD), FRAX without BMD, QFracture, Garvan, and the HKOS score, respectively. The category-less net reclassification index and integrated discrimination improvement of the HKOS score showed a better reclassification of hip fracture than FRAX and QFracture (all $P < 0.001$) but not Garvan, while Garvan, but not HKOS score, showed a significant over-estimation in fracture risk (Hosmer-Lemeshow test p -value <0.001). In the validation cohort, the HKOS score had a C-statistic of 0.81 and a considerable agreement between expected and observed fracture risk in calibration.

1
2
3
4 **Conclusion:** The HKOS score can predict 10-year incident hip fracture among the
5
6
7 oldest old in Hong Kong. The score may be useful in identifying the oldest old patients
8
9
10 at risk of hip fracture in both community-dwelling and hospital settings.

INTRODUCTION

Hip fracture is a leading cause of morbidity and mortality in the elderly. With an ageing world population, hip fracture will remain a huge public health problem. Our recent projection of hip fractures in major Asian countries using the most updated incidence rates and projected population sizes showed that the number of hip fractures will rise from 1.12 million in 2018 to 2.56 million in 2050, equivalent to a 2.28-fold increase (1). The direct cost associated with hip fracture is going to rise from 9.5 billion USD to 15 billion USD (1). In particular, the oldest old (defined as people aged 80 or above), who are among the most vulnerable to fracture (2), is the fastest growing age-group (3). According to a study performed by the World Health Organization, the proportion of countries with average life expectancy exceeding 80 was 6.6% in 2005, and it increased to 15.4% in 2015 (4). Prevention of hip fracture in the oldest old is therefore a key public health issue.

Many risk factors of hip fracture have been identified, yet most of them were based on epidemiological studies with a mean age of around 50 (5). Therefore, these findings may not be applicable to the oldest old, who have distinct features in terms of physiological functioning, comorbidity patterns and lifestyles (6, 7) while these are relatively rare in people aged below 80. Therefore, it remains largely unknown whether

1
2
3
4 conventional risk factors of hip fracture are still valid for the oldest old. We
5
6
7 hypothesized that the commonly used hip fracture prediction scores have limited
8
9
10 predictive ability in the oldest old population. To evaluate whether these conventional
11
12
13 risk factors can predict hip fracture in the oldest old and to derive an oldest-old specific
14
15
16 10-year hip fracture prediction risk score, we conducted a retrospective study among
17
18
19 participants of the Hong Kong Osteoporosis Study (HKOS) aged 80 or above who had
20
21
22 no history of hip fractures, with subsequent validation in an independent cohort
23
24
25 comprising of patients at high risk of osteoporotic fracture using robust statistical
26
27
28 analyses.
29
30
31
32
33

34 **MATERIALS AND METHODS**

36 **Participants**

37
38
39
40 HKOS is a prospective cohort study of osteoporosis in Hong Kong since 1995. Details
41
42
43 of HKOS have been described elsewhere (8). Ethical approval was obtained from the
44
45
46 Institutional Review Board, HKU/HA HKW, HKSAR, China. In brief, the cohort
47
48
49 participants were community-dwelling Southern Chinese men and women of Han
50
51
52 descent recruited from public road shows and health fairs held in various districts of
53
54
55 Hong Kong from 1995 to 2010. A total of 9,449 participants aged between 12 and 105
56
57
58 were recruited. Among all these participants, 387 were aged 80 or above and had no
59
60

1
2
3
4 history of hip fracture. After excluding those with missing data, 251 remained in the
5
6
7 final analysis and they had at least 10 years of follow up (Figure 1). Among the
8
9
10 excluded participants (N=136), most of them did not have their bone mineral density
11
12
13 (BMD) measured, either because they were too frail, chair-bound, or refused to have
14
15
16 dual-energy X-ray absorptiometry (DXA) scan. The risk score developed from the
17
18
19 derivation cohort was validated in an independent cohort.
20
21
22
23
24

25 **Risk Factor Selection**

26
27
28 Various risk assessment tools are currently available to evaluate one's probability of
29
30
31 fracture in 10 years, and the most widely used ones are FRAX, QFracture and Garvan,
32
33
34 which are all online available. FRAX was developed from population-based cohorts
35
36
37 from Europe, North America, Asia and Australia, that comprised of a total of 60,000
38
39
40 men and women (9). FRAX score is calculated from a country-specific algorithm,
41
42
43 which incorporates 12 readily available clinical risk factors of fracture and can be used
44
45
46 with or without BMD. QFracture was developed from a UK cohort study using data
47
48
49 from over 2 million men and women. QFracture included at least 24 risk factors in its
50
51
52 calculation but BMD is not used in the model (10). Garvan was developed using data
53
54
55 from an Australian cohort of approximately 2,500 men and women aged 60 years or
56
57
58 above. Unlike the other two scores, Garvan uses only five risk factors in the calculation
59
60

1
2
3
4 (11). Comparison of these risk scores has been discussed elsewhere (12) and the clinical
5
6
7 risk factors used in each score are shown in Supplementary Table 1. In our study, the
8
9
10 risk factors used in FRAX, QFracture and Garvan were analysed.
11
12
13
14
15

16 **BMD and Other Measurements**

17
18
19 BMD at the femoral neck was measured by DXA (Hologic QDR 4500 plus). Daily
20
21
22 calibration of the equipment was performed and the in vivo precision of DXA
23
24
25 measurement at the femoral neck was 1.5%. All other variables in the derivation cohort
26
27
28 were self-reported in a structured questionnaire with the help of a trained nurse or a
29
30
31 research assistant. Details have been described elsewhere (13). For the validation cohort,
32
33
34 data on the history of falls, history of non-hip fractures, and cerebrovascular accident
35
36
37 (CVA) were obtained from electronic medical records that have been validated (14,
38
39
40 15).
41
42
43
44
45

46 **Incident Hip Fracture**

47
48
49 Data of the hip fracture incidence were obtained from the database of the Hong Kong
50
51
52 Hospital Authority. The majority of the Hong Kong population attend the public
53
54
55 outpatient clinics and hospitals managed by the Hong Kong Hospital Authority (16). In
56
57
58 Hong Kong, 97.8% femoral fracture patients were admitted to hospitals under the Hong
59
60

1
2
3
4 Kong Hospital Authority (13). Hip fracture was identified using the ICD9 code 820.XX.
5
6

7 We previously validated the records of hip fracture coding with a positive predictive
8
9
10 value of 100% (14).
11
12
13
14
15

16 **Statistical Analyses**

17
18

19 We developed a 10-year sex-specific risk prediction score of hip fracture using logistic
20
21
22 regression. The final prediction model was built using the forward stepwise selection
23
24
25 procedure based on p-value, effect size, and clinical importance of the variables.
26
27

28 Survival time was calculated from the baseline date to the date of diagnosis of hip
29
30
31 fracture, death, or end of study (10 years of follow up time for the derivation cohort).
32
33

34 Bias-corrected accelerated 95% CI and p-value were estimated by 500 bootstrap
35
36
37 resamples. Due to the high risk of mortality in the oldest old, competing risk of death
38
39
40 may affect the validity of the findings. As a sensitivity analysis, competing risk
41
42
43 regression was used.
44
45
46
47
48

49 A predicted probability (the HKOS score) of hip fracture for the oldest old was
50
51
52 generated. The beta-estimates from the final logistic regression model were used as the
53
54
55 weights of the risk factors and combined with the intercept to generate the HKOS score
56
57
58 in the derivation cohort. On the other hand, calculations of FRAX
59
60

1
2
3
4 (<https://www.sheffield.ac.uk/FRAX/tool.aspx?country=20>), QFracture
5
6
7 (<https://qfracture.org/>) and Garvan ([https://www.garvan.org.au/promotions/bone-](https://www.garvan.org.au/promotions/bone-fracture-risk/calculator/)
8 [fracture-risk/calculator/](https://www.garvan.org.au/promotions/bone-fracture-risk/calculator/)) risk scores were done using their online calculators. These
9
10 fracture prediction scores provided prediction for “any osteoporotic fracture” and “hip
11
12 fracture”, and the risk score of hip fracture was recorded for the current analysis.
13
14 Harrell’s C-statistics were then calculated to evaluate the discriminative ability of the
15
16 HKOS score, FRAX with BMD, FRAX without BMD, QFracture and Garvan, and the
17
18 statistical differences between C-statistics were compared using the Z-score test. The
19
20 improvement in discrimination for incident hip fracture was evaluated by using
21
22 category-less net reclassification index (NRI) and integrated discrimination
23
24 improvement (IDI). Category-less NRI was used because it is considered the most
25
26 objective and versatile measure of improvement in risk prediction (17). The R package
27
28 “Hmisc” was used for the analysis. The performance of the HKOS score was further
29
30 evaluated by calibration using the Hosmer-Lemeshow statistics. We divided the cohort
31
32 into 5 groups based on the quintiles of predicted fracture risk, and provided calibration
33
34 plots of predicted versus observed fracture risks.
35
36
37
38
39
40
41
42
43
44
45
46
47
48
49
50
51
52
53
54

55 **Model Validation**

56
57
58 The performance of the HKOS score was validated in an independent validation cohort.
59
60

1
2
3
4 The validation cohort was a retrospective cohort from the Osteoporosis Centre in Queen
5
6
7 Mary Hospital, which consisted of patients at high risk of osteoporotic fracture being
8
9
10 referred to have a DXA scan and management in the Osteoporosis Centre. All patient
11
12
13 identities were anonymized, and electronic medical records were linked to patients'
14
15
16 details using a unique anonymized reference key. We identified patients aged 80 or
17
18
19 above who had femoral neck BMD measured (N=1,085). After excluding patients with
20
21
22 history of hip fracture (N=465) or with missing data (N=26), 599 participants remained
23
24
25 in the final analysis (Figure 1). A comparison of basic demographics and risk factors
26
27
28 in the final prediction model between the derivation and validation cohorts is shown in
29
30
31 Supplementary Table 2. The Harrell's C-statistics and area under ROC curve (AUC)
32
33
34 were determined. Z-score (for Harrell's C-statistics) and deLong tests (for AUC) were
35
36
37 used to compare the C-statistics of the HKOS score with other existing fracture
38
39
40 prediction risk scores. A corrected HKOS score based on follow-up time was derived
41
42
43 for calibration. All statistical analyses were conducted using SPSS Version 22.0
44
45
46 software (IBM, Inc., Chicago, IL, USA) and R (R Foundation for Statistical Computing,
47
48
49 Vienna, Austria; <https://www.r-project.org/>).

55 **RESULTS**

58 **Participants in the Derivation Cohort**

1
2
3
4 After a median follow-up time of 8.9 years (1,801.4 person-years in total), 40
5
6
7 participants had an incident hip fracture, with an overall incidence rate of 22.2 per 1,000
8
9
10 person-years. Those with incident hip fracture were more likely to be female, with
11
12
13 lower body weight, lower BMD at femoral neck, history of falls over last 12 months,
14
15
16 history of non-hip fracture, CVA, higher FRAX score, higher QFracture score, and
17
18
19 higher Garvan score (Table 1 and Supplementary Table 3).
20
21
22
23
24

25 **Association and Model Development**

26
27
28 Results of the logistic regression models are shown in Table 2. Female sex, lower
29
30
31 weight, lower BMD at femoral neck, history of falls over last 12 months, history of
32
33
34 non-hip fracture and CVA were significantly associated with increased risk of hip
35
36
37 fracture in the crude model. Using forward stepwise regression, the final prediction
38
39
40 model comprised of femoral neck BMD (OR 0.47; 95% CI 0.32-28.01), history of non-
41
42
43 hip fracture (OR 2.44; 95% CI 1.01-5.87), and CVA (OR 5.94; 95% CI 1.26-28.01)
44
45
46 (Table 2). Well established risk factors, such as age, sex, and weight, were not
47
48
49 significantly associated with hip fracture and not included in the final model
50
51
52 (Supplementary Table 4). The bias-corrected p-values were generally similar to the
53
54
55 conventional logistic regression analysis. We selected variables with p-value < 0.1 in
56
57
58 the final model to estimate the HKOS score. These included femoral neck BMD, history
59
60

1
2
3
4 of non-hip fracture, CVA, height, and history of falls over last 12 months. Given that
5
6
7 sex-specific association was observed, we used the beta estimates and intercept of the
8
9
10 sex-specific model to calculate the HKOS score (Supplementary Table 5).

11
12
13
14
15
16 Comparison of the C-statistic of the HKOS score (femoral neck BMD + height + history
17
18 of falls + history of non-hip fractures + CVA) with that of FRAX with BMD, FRAX
19
20 without BMD, QFracture and Garvan is shown in Table 3. The HKOS score (C-statistic:
21
22 0.78; 95% CI: 0.72-0.84) had the highest yet comparable C-statistic with other
23
24
25 prediction scores, followed by Garvan, QFracture, FRAX with BMD, and FRAX
26
27
28 without BMD with C-statistics of 0.76 (95% CI: 0.70-0.81), 0.65 (95% CI: 0.58-0.73),
29
30
31 0.65 (95% CI: 0.58-0.72) and 0.61 (95% CI: 0.53-0.69), respectively. Using the Z-score
32
33
34 test, the HKOS score was more concordant with the outcome when comparing with
35
36
37 other fracture prediction scores (all $P < 0.05$; Table 3), except that similar C-statistics
38
39
40 were observed between HKOS score and Garvan (Table 3). Similar results were
41
42
43 observed using AUC and deLong test (Supplementary Table 6).

44
45
46
47
48
49
50
51
52 Table 4 shows the category-less NRI and IDI of the HKOS score when compared with
53
54
55 FRAX with BMD, FRAX without BMD, QFracture and Garvan respectively. The
56
57
58 category-less NRI and IDI showed that the HKOS score had an improved
59
60

1
2
3
4 reclassification of incident hip fracture when compared with FRAX with BMD (NRI:
5
6
7 0.672; IDI: 0.109), FRAX without BMD (NRI: 0.913; IDI: 0.153), and QFracture (NRI:
8
9
10 0.470; IDI: 0.142) (all $P < 0.001$). No significant difference in performance was
11
12
13 observed between the HKOS score and Garvan.

19 **Model Calibration**

20
21
22 The calibration plots demonstrated considerable agreement between the predicted and
23
24
25 observed fracture risks of the HKOS score in the derivation cohort (Hosmer-Lemeshow
26
27
28 test p-value: 0.638; Figure 2a). Although Garvan showed a similar NRI and IDI to the
29
30
31 HKOS score, it significantly over-estimated the risk of fracture (Hosmer-Lemeshow
32
33
34 test p-value: < 0.001), as shown in the calibration plots (Supplementary Figure 1).
35
36
37
38
39

40 **Association and Model Validation in the Validation Cohort**

41
42
43 After a median follow-up time of 2.6 years (2,1965.9 person-years in total), 29
44
45
46 participants had an incident hip fracture, with an overall incidence rate of 13.2 per 1,000
47
48
49 person-years. Baseline characteristics of the validation cohort have been shown in
50
51
52 Supplementary Table 7.
53
54
55
56
57

58 In the independent validation cohort, BMD at femoral neck (OR: 0.59; 95% CI: 0.39-
59
60

1
2
3
4 0.89), history of falls over last 12 months (HR: 3.54; 95% CI: 1.44-8.69), and CVA
5
6
7 (HR: 3.89; 95% CI: 1.45-10.42) were also significantly associated with the first hip
8
9
10 fracture in the oldest old (Supplementary Table 8). In addition, using competing risk
11
12
13 regression as a sensitivity analysis, similar results were observed (Supplementary Table
14
15
16 9).

21
22 Using the intercept and beta-estimates from the derivation cohort, the HKOS score was
23
24
25 calculated in the validation cohort. The Harrell's C-statistic of the HKOS score in the
26
27
28 validation cohort (Harrell's C-statistic: 0.81; 95% CI: 0.75-0.87) was even higher than
29
30
31 that in the derivation cohort. Moreover, the calibration plots showed considerable
32
33
34 agreement between predicted and observed fracture risks in the validation cohort
35
36
37 (Hosmer-Lemeshow test p-value: 0.528; Figure 2b).

43 **DISCUSSION**

46 **Summary of Key Findings**

48
49 This study evaluated the conventional risk factors for prediction of hip fracture in the
50
51
52 oldest old and the discriminative performances of the risk scores for incident hip
53
54
55 fracture. It was found that the HKOS score comprising of BMD at femoral neck, height,
56
57
58 history of falls over last 12 months, history of non-hip fractures, and CVA might be a
59
60

1
2
3
4 good predictor of 10-year hip fracture risk in the oldest old, and the finding was
5
6
7 subsequently validated in an independent validation cohort in a separate setting. Other
8
9
10 well-established risk factors such as age, sex, and weight were not significantly
11
12
13 associated with hip fracture in the oldest old. The commonly used hip fracture
14
15
16 prediction scores showed limited predictive ability of hip fracture in the oldest old.
17
18
19

20 21 22 **Risk factors of Hip Fracture Among the Oldest Old** 23

24
25 In the development of the HKOS score, five risk factors were included in the final
26
27
28 model. Among the five risk factors, BMD, height, history of fall, and history of fracture
29
30
31 are well-established risk factors of hip fracture (18). Yet, CVA is comparatively less
32
33
34 recognized as a risk factor of fracture, which is only used for calculating QFracture.
35
36
37 Stroke survivors are known to have a higher risk of fracture, owing to impairments in
38
39
40 balance, sensory and motor functions, and hence predisposing them to falls (19). This
41
42
43 also explains why the effect of history of falls, which was significantly associated with
44
45
46 incident hip fracture in the crude model, was attenuated after adjustment for CVA.
47
48
49 Moreover, we previously also showed that warfarin, a drug commonly used for stroke
50
51
52 prevention, was associated with increased risk of fracture (20). Reduction in BMD in
53
54
55 stroke survivors also contributed to their higher fracture rates (21, 22).
56
57
58
59
60

1
2
3
4 Both history of falls and history of non-hip fractures were significantly associated with
5
6
7 incident hip fracture in the crude model, but the associations became statistically
8
9
10 insignificant in the full model. We further investigated these two factors in the
11
12
13 derivation and validation cohort. The results showed that these risk factors were both
14
15
16 significantly associated with incident hip fracture in the crude model. However, history
17
18
19 of falls became statistically insignificant after mutual adjustment in the derivation
20
21
22 cohort, whereas history of non-hip fracture became statistically insignificant in the
23
24
25 validation cohort (Supplementary Table 10). These findings suggest that both history
26
27
28 of falls and history of non-hip fractures are dependent on each other and captured
29
30
31 common information.
32
33
34
35
36

37 Age is not a significant predictor of incident hip fracture in the oldest old. Age is
38
39
40 included in all hip fracture prediction scores, whereas our previous study also showed
41
42
43 that age is a significant predictor of hip fracture in the HKOS participants with a mean
44
45
46 age of 63.4 (23). However, it seems that it is no longer useful in predicting hip fracture
47
48
49 in the oldest old, which is in agreement with a recent study of nursing home residents
50
51
52 (mean age of 83.9) showing that age contributed modestly towards the risk of hip
53
54
55 fracture (24), compared with other community-based studies. Indeed, the null
56
57
58 association of age with clinical outcomes (such as mortality in critically-ill patients (25))
59
60

1
2
3
4 and blood pressure decline) have been well reported in the oldest old, in which overall
5
6
7 health status (26) or biological age (13), instead of chronological age, may be a more
8
9
10 important factor in predicting clinical outcomes.
11
12
13

14 15 16 **Comparison with Existing Risk Prediction Scores** 17

18
19 Garvan had a similar performance in predicting fracture risk to the newly-derived
20
21 HKOS score. Same as the HKOS score, the Garvan score is calculated from five risk
22
23 factors, in which three of them (history of falls, history of fractures, and BMD) were
24
25 also incorporated in the HKOS score, which may explain the similar performance in
26
27 reclassification of fracture risk. Regarding the calibration plot, the Garvan score was
28
29 inferior to that of the HKOS score, in which Garvan significantly over-estimated the
30
31 risk. The development of Garvan score was based on a different population (Australian),
32
33 thus the estimates derived from Garvan are not applicable in the oldest old Chinese
34
35 population. Although the Harrell's C-statistic of the HKOS score was the highest
36
37 among various prediction scores, its 95% confidence interval overlapped with that of
38
39 Garvan, QFracture, and FRAX with BMD. This suggested HKOS score has similar
40
41 discriminative performance when compared with the above prediction scores. On the
42
43 other hand, the HKOS may have better risk reclassification than FRAX and QFracture
44
45 in predicting incident hip fracture. This again highlighted the importance of the current
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3
4 study in deriving an oldest-old specific fracture risk prediction score. The FRAX
5
6
7 algorithm was originally developed from 11 Caucasian and 1 Japanese prospective
8
9
10 cohort studies (27), and the mean age in the majority of these studies was 50-65 years
11
12
13 (5). Our previous study showed that ethnic-specific clinical risk factors may be more
14
15
16 important than FRAX in predicting fracture (28). The difference in age-group and
17
18
19 ethnicity of FRAX's development cohorts may therefore explain its relatively low
20
21
22 accuracy of FRAX in predicting fracture in the oldest old in Hong Kong. Similarly, the
23
24
25 mean age of the cohorts deriving QFracture and Garvan was 50 (10) and 70 (11),
26
27
28 respectively. This may explain why Garvan had a better predictive ability than FRAX
29
30
31 and QFracture in the oldest old (data not shown). On the other hand, although the
32
33
34 calculation of QFracture includes CVA, its ability in predicting hip fracture in the oldest
35
36
37 old was modest in the current study. This could be because QFracture was developed
38
39
40 from the UK population, and it consists of 21 clinical variables in addition to age, sex,
41
42
43 ethnicity, and BMI. Among these variables, only three were significantly associated
44
45
46 with hip fracture in the current study. Inclusion of additional predictors which are not
47
48
49 associated with hip fracture in the calculation of QFracture may indeed introduce noise
50
51
52 to the prediction.
53
54
55
56
57

58 **Implications for Clinical Practice**

59
60

1
2
3
4 This study has several clinical significances. To the best of our knowledge, this is the
5
6
7 first study to evaluate the performances of various risk prediction scores in predicting
8
9
10 hip fracture in the oldest old, and to derive a 10-year risk score for predicting the first
11
12
13 hip fracture in the oldest old with validation. Notably, the settings of the derivation and
14
15
16 validation cohorts were very much different. The derivation cohort was a cohort study
17
18
19 in the community setting, whereas the validation cohort was a retrospective cohort
20
21
22 study in the hospital setting. Those participants in the validation cohort had osteoporosis
23
24
25 or were at high risk of fracture being referred to DXA scan and management by
26
27
28 physicians. Thus, it was shown that the incidence of hip fracture was lower in the
29
30
31 validation cohort (13.2 and 22.24 per 1,000 person-years in validation and derivation
32
33
34 cohorts, respectively). Together with the considerable calibration data, these findings
35
36
37 suggest that the HKOS score may be useful in predicting hip fracture in both
38
39
40 community-dwelling and hospital settings.
41
42
43
44
45

46 **Strengths and Limitations**

47
48
49 This study has several other strengths. The HKOS is a prospective cohort study of
50
51
52 osteoporosis, and hence many osteoporosis-related risk factors are included in the study
53
54
55 (8). The findings of our study were independently validated in a validation cohort which
56
57
58 comprised of a group of high-risk patients from hospitals, suggesting the
59
60

1
2
3
4 generalizability of the findings. Secondly, the detection of hip fracture was validated
5
6
7 with high accuracy (14). Thirdly, this study had a long follow up time (10 years) for the
8
9
10 oldest old, which would be difficult to achieve in other places where life expectancies
11
12
13 are shorter. Fourthly, since external validation by other cohorts is expected to be
14
15
16 difficult in the oldest old with a long follow up time, bootstrapping was first performed
17
18
19 as internal validation. Similar results observed in 500 bootstrap resamples, together
20
21
22 with subsequent validation in the validation cohort, suggest that the findings are robust.
23
24
25 Fifthly, due to competing risk of death, competing risk regression was used to account
26
27
28 for the effects of risk of death on risk of hip fracture, and similar results were observed.
29
30
31

32
33
34 Nevertheless, there are several limitations. First, with only 40 events in the derivation
35
36
37 cohort, the power was limited to the extent that we could only identify risk factors with
38
39
40 large effect size. It is possible that other risk factors with a smaller effect size may also
41
42
43 predict hip fracture, especially those categorical variables that are less common. Thus,
44
45
46 it is possible that the prediction performance of FRAX and QFracture may be improved
47
48
49 in a larger sample size. Similarly, there were only 29 hip fracture events in the
50
51
52 validation cohort. Thus, the HKOS score may behave very differently in other cohorts,
53
54
55 and future validation study in other population is warranted. Secondly, there are no data
56
57
58 for some of the variables used in the calculation of QFracture and assumptions had to
59
60

1
2
3
4 be made. For example, we do not have data regarding a history of epilepsy or
5
6
7 anticonvulsant use. However, given that the annual incidence rate of epilepsy in Asian
8
9
10 elderly is only around 1.6 per 1 000, it is reasonable for us to assume that there are no
11
12
13 patients with a history of epilepsy in our study group of 251 participants. There were
14
15
16 data on COPD but not asthma, therefore we could not evaluate the predictive ability of
17
18
19 asthma. In addition, our study does not have data on bone microarchitecture (29),
20
21
22 trabecular bone score (30), diet (31), and cognitive impairments (32), which may be
23
24
25 important for hip fracture prediction. Furthermore, there was quite a large proportion
26
27
28 of missing data in the derivation cohort, mostly because those participants were too frail
29
30
31 or chair-bound to have their BMD measured, or refused to have DXA measurement.
32
33
34 However, multiple imputation was not performed. This is because frailty itself is
35
36
37 associated with an increased risk for fracture (33), so these participants would already
38
39
40 have a higher fracture risk than the rest of the derivation cohort, potentially rendering
41
42
43 the results of imputation invalid. This also means that the HKOS score may not be
44
45
46 applicable in predicting fracture risk in the oldest old who are already too frail. Yet this
47
48
49 would not undermine the clinical utility of this score because frail individuals would
50
51
52 generally be under special care to minimize fracture risk even without the aid of a
53
54
55 clinical risk score. On the other hand, since both the derivation and validation cohorts
56
57
58 were ethnically Chinese, the extent to which the HKOS score can be applied to other
59
60

1
2
3
4 ethnic groups remains unknown. Thus, future validation studies in other ethnic groups
5
6
7 are needed. Besides, it is unclear if other advanced statistical modeling, such as machine
8
9
10 learning approach, can derive a risk score with higher accuracy. However, a recent
11
12
13 systematic review suggests that machine learning approach is not necessarily better than
14
15
16 the conventional logistic regression approach (34). Finally, like other observational
17
18
19 studies, there may be residual confounding effects.
20
21
22
23
24

25 **Conclusions**

26
27
28 In conclusion, the HKOS score derived from the five predictors can predict 10-year
29
30
31 incident hip fracture in the oldest old. The good performance of HKOS score was
32
33
34 replicable in terms of C-statistics and calibration in the independent validation cohort.
35
36
37 These findings suggest that HKOS score may be useful in identifying oldest old patients
38
39
40 at risk of hip fracture in both community-dwelling and hospital settings. Our study calls
41
42
43 for more research not only to further validate these findings, but also to focus on
44
45
46 research on hip fracture in the oldest old, which is associated with extremely high
47
48
49 mortality and treatment cost and reduction in quality of life.

Table 1. Baseline characteristics of the derivation cohort

	Without hip fracture (N = 211)	With hip fracture (N = 40)	p-value
Female	122 (57.8%)	31 (77.5%)	0.022
Weight (kg)	53.46 (10.04)	49.62 (9.99)	0.027
BMD at femoral neck (g/cm ²)	0.56 (0.13)	0.46 (0.09)	<0.001
History of falls over last 12 months	57 (27%)	18 (45%)	0.025
History of non-hip fracture	88 (41.7%)	30 (75%)	<0.001
Cerebrovascular accident	4 (1.9%)	4 (10%)	0.017
FRAX	10.42 (8.36)	15.27 (9.88)	0.002
QFracture	8.62 (6.44)	11.88 (6.12)	<0.001
Garvan	22.93 (24.26)	44.95 (26.59)	0.003

Note - Data are presented as mean \pm SD for continuous variables, and frequency (percentage) for categorical variables.

Only variables showing significant differences are shown. Full table is provided as Supplementary Table 2.

Table 2. Association of conventional risk factors with incident hip fracture

Variables ^a	Crude model			Full model ^b			
	OR	95% CI	p-value	OR	95% CI	p-value	Bootstrap p-value ^c
Female	2.51	(1.14-5.54)	0.022				
Height (m)	0.09	(0.00-3.01)	0.176	64.16	(0.48-8500.29)	0.095	0.086
Weight (kg)	0.96	(0.93-1.00)	0.029				
BMD at femoral neck (per 0.1 g/cm ²)	0.50	(0.36-0.69)	<0.001	0.47	(0.32-28.01)	<0.001	0.002
History of falls over last 12 months	2.21	(1.11-4.42)	0.025	1.96	(0.90-4.25)	0.089	0.094
History of non-hip fracture	4.19	(1.95-9.02)	<0.001	2.44	(1.01-5.87)	0.047	0.064
Cerebrovascular accident	5.75	(1.38-24.04)	0.017	5.94	(1.26-28.01)	0.025	0.002
Cancer	3.24	(0.90-11.63)	0.072

^a Variables with $P < 0.1$ are shown.

^b Five predictors were selected based on forward stepwise regression.

^c Internal validation of the multivariable logistic regression model by 500 bootstrap resamples.

For Peer Review

Table 3. Harrell's C-statistics of the final prediction model, FRAX, QFracture and Garvan in the derivation cohort

	Harrell's C-statistics	Z-score test P-value*
Combined Model (HKOS score)	0.78 (0.72-0.84)	Ref
FRAX	0.65 (0.58-0.72)	<0.001
FRAX without BMD	0.61 (0.53-0.69)	<0.001
QFracture	0.65 (0.58-0.73)	0.006
Garvan	0.76 (0.70-0.81)	0.383

* Z-score test was used to compare the C-statistics of the combined model with other existing fracture prediction risk scores.

Table 4. Comparative performance metrics (category-less NRI and IDI) for predicting incident hip fracture in the derivation cohort

Statistics	Compared with	Estimates	p value
Category-Less NRI	FRAX with BMD	0.672 (0.379-0.965)	<0.001
	FRAX without BMD	0.913 (0.656-1.171)	<0.001
	QFracture	0.470 (0.228-0.713)	<0.001
	Garvan	0.066 (-0.188-0.319)	0.612
IDI	FRAX with BMD	0.109 (0.052-0.166)	<0.001
	FRAX without BMD	0.153 (0.088-0.219)	<0.001
	QFracture	0.142 (0.078-0.207)	<0.001
	Garvan	-0.045 (-0.122-0.031)	0.246
