TECHNICAL NOTE

Pore pressure coefficient for soil and rock and its relation to compressional wave velocity

J. YANG*

KEYWORDS: compressibility; dynamics; laboratory tests; partial saturation; pore pressures

INTRODUCTION

In laboratory triaxial tests it has been common to check the specimen's degree of saturation by determining the pore pressure coefficient, $B$. The method is known as the $B$-value test and basically originated from Skempton's work on evaluation of the pore pressures in clays in the design of earth dams, in which he derived the well-known expression for $B$ (Skempton, 1954):

$$B = \frac{\Delta \sigma}{\sigma} = \frac{1}{1 + n(K_b/K_f)}$$

(1)

Here $\Delta \sigma$ is a small increase in all-round or confining pressure applied to an element of soil in an earth dam or to the sample in the tests, and $\Delta \sigma$ is the resulting change in pore pressure measured under undrained conditions. The porosity of soil is denoted in equation (1) by $n$. $K_b$ denotes the bulk modulus of the soil skeleton, and $K_f$ the bulk modulus of the mixture of pore water and air.

Since the compressibility of water is negligible compared with that of the soil skeleton, equation (1) indicates that $B \approx 1$ for saturated soils, whereas for partially saturated soils $0 < B < 1$, with a typical range of 0.1 to 0.5 at the optimum water content.

In deriving equation (1) the solid grains were assumed as incompressible, which has been a widely accepted assumption in soil mechanics, but may not be applicable in rock mechanics. For soils and rocks with compressible particles, Bishop (1973) showed later on that the pore pressure coefficient was expressed by

$$B = \frac{\Delta \sigma}{\sigma} = \frac{1}{1 + n(K_b - 1/K_f)}$$

(2)

in which $K_s$ is the bulk modulus of solid particles.

Recently, Kokusho (2000) presented the following expression for $B$ using Biot's formulation given by Zienkiewicz & Bettess (1982):

$$B = \frac{1/K_b - 1/K_s}{1/K_b + n/K_f - n/K_s}$$

(3)

It is not difficult to note that equation (3) differs from Bishop's expression when the latter is written in an alternative form as

$$B = \frac{1/K_b - 1/K_s}{1/K_b + n/K_f - (1 + n)/K_s}$$

(4)

Since Biot's theory describes the behaviour of porous media such as soils and rocks more rigorously, a concern naturally arises over the correctness of either Bishop's or Kokusho's expression, as well as the cause leading to the difference between them. It is the purpose of the present study to clarify this issue, both analytically and numerically.

Besides the pore pressure parameter $B$, a new indicator of saturation for soils—the velocity of compressional waves (i.e. P-waves), $V_p$—has been advocated, and has received increasing attention (Yang & Sato, 1998, 2000a; Kokusho, 2000; Ishihara et al., 2001). Compared with the pore pressure parameter $B$, the P-wave velocity can be measured conveniently in the field and thus has an advantage in practical applications. The effectiveness of the use of P-wave velocity in identifying in-situ partially saturated zones has been well demonstrated by a borehole array site (Yang & Sato, 2000a). More recently, an application of P-wave velocity in interpreting laboratory test data for the cyclic strength of partially saturated sands has been proposed by Yang (2002), who showed a useful relation between $B$ and $V_p$:

$$V_p = \frac{[4\mu/3 + K_b/(1 - B)]^{1/2}}{\rho}$$

(5)

in which $\mu$ (or $G$) is the shear modulus of the soil skeleton and $\rho$ is total mass density.

In deriving equation (5) the compressibility of solid grains was not of primary concern and therefore not included in the expressions for either $B$ or $V_p$. In this study a general relation between $B$ and $V_p$ will be established within the framework of Biot's theory, and the effect of particle compressibility will be identified numerically. This is a second purpose of the present study.

DERIVATION OF PORE PRESSURE PARAMETER

The analysis is based on classical Biot's theory (Biot, 1956, 1962), which models the complex interactions between the solid and fluid parts using the macroscopic laws of mechanics. In its simplest form the analysis requires the following assumptions:

(a) The porous medium is statistically isotropic in such a way that for any cross-section the same ratio of the fluid area to the solid area applies.

(b) The void space of the porous medium is interconnecting, and the sealed pore space is part of the solid.

(c) Both the solid skeleton and the solid material forming it are elastic and isotropic.

(d) The solid grains, solid skeleton and pore fluid are compressible.

(e) The pore fluid is viscous, and Darcy's law governs its flow.
It is customary to denote the displacement of the solid part by \( u_i \) and the displacement of fluid relative to the solid by \( w_i \). Thus the field equations accounting for both inertial and viscous interactions between the two parts in the porous medium can be given as

\[
\mu u_{ij} + (\lambda + \alpha^2 M + \mu) e_{ij} - \alpha M \zeta_{ij} = \rho u_i + \rho_t w_i \tag{6}
\]

\[
\alpha Me_{ij} - M \zeta_{ij} = \rho_t u_i + \frac{\rho_t}{n} w_i + \frac{\eta}{K} \dot{w}_i \tag{7}
\]

where \( e = u_{ij,j} \) and \( \zeta = -w_{ij,j} \); \( \rho_s \) is the mass density of solid grains, \( \rho_t \) is the mass density of fluid, and \( \rho = (1 - n) \rho_s + \rho_t \); \( \lambda \) is the Lamé constant of the solid frame; and \( \alpha \) and \( M \) are parameters accounting for the compressibilities of solid and fluid constituents, and given by

\[
\alpha = 1 - \frac{K_b}{K_s} \tag{8}
\]

\[
M = \frac{\frac{K_s^2}{K_s^3}}{\left[1 + n \left( \frac{K_s}{K_f} - 1 \right) \right] - K_b} \tag{9}
\]

Obviously, for incompressible solid grains \( \alpha = 1 \) and \( 1/M = n/K_s \).

Note that \( k' \) in the field equations differs from the permeability coefficient \( k \) (m/s) that is used in soil mechanics. They are related by

\[
k' = k \frac{\eta}{\rho V g} \tag{10}
\]

in which \( \eta \) is fluid viscosity and \( g \) is the gravitation acceleration at which the permeability is measured.

The field equations (6) and (7) have been obtained by entering into the equilibrium conditions the following relationships between stress, pore pressure, and strain:

\[
\sigma_{ij} = \lambda e_{ij} + 2\mu e_{ij} - \alpha \delta_{ij} p_t \tag{11}
\]

\[
p_t = M \zeta_{ij} - \alpha Me_{ij} \tag{12}
\]

where \( \sigma_{ij} \) is the stress tensor, \( e_{ij} = (u_{ij,j} + u_{j,i,j})/2 \) is the strain tensor, \( p_t \) is pore pressure, and \( \delta_{ij} \) is the Kronecker delta.

Here a concept of homogenisation has been introduced that assumes that the mixture of pore water and air can approximately be treated as an equivalent homogeneous pore fluid completely filling the voids with a single pore pressure. Note that equation (11) implies the effective stress law in the following form:

\[
\sigma_{ij} = \sigma_{ij}' - \delta_{ij} \alpha p_t \tag{13}
\]

in which \( \sigma_{ij}' \) is the effective stress tensor. Clearly, equation (13) can be reduced to the well-known effective stress equation introduced by Terzaghi if the compressibility of solid grains is ignored.

Equation (12) can readily be rewritten as

\[
w_{i,j} = au_{i,j} + \frac{p_t}{M} \tag{14}
\]

By specifying the undrained conditions that there is no flow of pore fluid, one arrives at

\[
a u_{i,j} + \frac{p_t}{M} = 0 \tag{15}
\]

or

\[
\left(1 - \frac{K_s}{K_e}\right) \frac{\alpha_j}{3 K_b} + \left( \frac{\alpha}{K_s} + \frac{n}{K_f} - \frac{n}{K_s} \right) p_t = 0 \tag{16}
\]

Introducing the effective stress law expressed in equation (13) into the above equation leads to

\[
\frac{1}{K_b} - \frac{1}{K_s} \left( \frac{\alpha_j}{3 K_b} \right) + \left( \frac{n}{K_f} - \frac{n}{K_s} \right) p_t = 0 \tag{17}
\]

from which the pore pressure coefficient can readily be derived as

\[
B = -\frac{3 p_t}{\alpha_j} = \frac{1}{K_b} - \frac{1}{K_s} \tag{18}
\]

Note that the negative sign is required by the sign convention embedded in equation (11).

Now, it is of interest to observe that the expression derived above is the same as that by Bishop (1973), implying that the expression due to Kokusho (2000) is in error. It is found that a major cause of the error was incorrect use of the effective stress law: the effective stress equation by Terzaghi rather than the general form in equation (13) was used, and a consistency was lost.

Furthermore, by introducing the commonly used expression for the compressibility of pore fluid (Yang & Sato, 1998, 2000a),

\[
\frac{1}{K_f} = \frac{1}{K_w} + \frac{1}{p_s} - S_t \tag{19}
\]

where \( S_t \) is the degree of saturation, \( K_w \) is the bulk modulus of pore water, and \( p_s \) is the absolute fluid pressure, equation (18) can be written as a function of saturation:

\[
B = \frac{1}{K_b} - \frac{1}{K_s} \tag{20}
\]

### A GENERAL EXPRESSION FOR COMPRESSIONAL WAVE VELOCITY

In the same context of Biot’s theory, the field equations (6) and (7) can be solved with the aid of potential functions, yielding two compressional waves and one shear wave. In the low-frequency range to which the frequencies involved in most soil dynamics problems belong, only the fast compressional wave exists, with its velocity being independent of frequency, while the slow one is a diffusion process owing to the viscous coupling between the solid and fluid phases. The interested reader may refer to Yang & Sato (2000b), where more details about the two compressional waves are presented, with a special reference to the vibration of a soil column.

The velocity of the fast compressional wave at low frequencies is given by (Yang & Sato, 2000a)

\[
V_p = \left( \frac{\lambda + 2\mu + \alpha^2 M}{\rho} \right)^{1/2} \tag{21}
\]

It can be verified that for a limiting case of incompressible grains the above expression takes the form as given in Yang (2002):

\[
V_p = \left( \frac{\lambda + 2\mu + K_f/n}{\rho} \right)^{1/2} \tag{22}
\]

Similarly, the general expression in equation (21) can be written as a function of the degree of saturation as

\[
V_p = \left[ \frac{K_b + 4\mu/3}{\rho} + \frac{\alpha^2}{\rho (\alpha - n)K_s + n/K_w + n(1 - S_t)p_s} \right]^{1/2} \tag{23}
\]

For a fully saturated porous medium with incompressible
particles, equation (23) reduces to the following simple form:

$$V_p = \left( \frac{K_b + 4\mu/3 + K_w/n}{\rho} \right)^{1/2}$$

(24)

With equations (18) and (21) in hand a general relationship between $B$ and $V_p$ can be obtained:

$$V_p = \left( \frac{4\mu/3 + K_b/(1 - \alpha B^2)}{\rho} \right)^{1/2}$$

(25)

To the author’s knowledge, equation (25) is the first proposal of the explicit relationship between $B$ and the bulk modulus of the skeleton, $K_b$, from Biot’s theory. It can be shown that in a framework of Biot’s theory. It can be shown that in a limiting case of incompressible grains this general relation becomes the simple one given by Yang (2002).

An alternative form for the above expression can be given by introducing the shear wave velocity, $V_s$, an engineering property directly linked with the shear modulus of soil and rock:

$$B = \frac{1}{\alpha} \left[ 1 - \frac{3K_b}{\rho(3V_s^2 - 4V_p^2)} \right]$$

(26)

EFFECT OF PARTICLE COMPRESSIBILITY

The influence of particle compressibility, skeleton compressibility and porosity on the value of $B$ at full saturation is illustrated in Fig. 1(a), where comparison of the values given by Skempton’s expression (equation (1)) and by equation (18) is included. Here the bulk modulus of solid particles is assumed as a typical value (i.e. $K_w = 36$ GPa), and the bulk modulus of the skeleton, $K_b$, is normalised by $K_s$. For purposes of comparison, the values calculated by equation (3) (Kokusho’s expression) are presented together with those given by equation (18) in Fig. 1(b).

It is interesting to note from Fig. 1(a) that for porous media of high skeleton compressibility, say $K_b/K_s < 0.1$, the difference between the values of $B$ given by equations (1) and (18) is not significant. In other words, whether or not the particle compressibility is taken account of will not impact on the prediction of $B$. However, as the skeleton compressibility approaches the compressibility of solid grains, major errors will arise from the neglect of the particle compressibility. Indeed, a wide range of the skeleton compressibility has been reported for porous or fissured rocks, for which it is not uncommon that $K_b/K_s$ may be of the order of 0.5.

Figure 1(a) also indicates that, at a specific large value of $K_b/K_s$, the difference caused by neglect of the particle compressibility is sensitive to the value of porosity. The difference will become much greater as the porosity decreases, with Skempton’s expression giving a higher value of $B$.

Based on the general expression given in equation (20), the relation between the pore pressure ratio $B$ and the degree of saturation $S$, is plotted in Fig. 2 for various values of $K_b/K_s$, where Fig. 2(a) is for a porosity of 0.35 and Fig. 2(b) for a porosity of 0.05. In the calculation the absolute fluid pressure is taken as the atmospheric pressure. It is clear from Fig. 2 that at a specific degree of saturation the value of $B$ is strongly dependent on the ratio of $K_b/K_s$. For example, for the porous medium with a porosity of 0.05, $B$ at full saturation is about 0.999 for $K_s/K_b = 0.001$, but only 0.565 for $K_s/K_b = 0.5$. On the other hand, Fig. 2 implies that, for a specific value of $B$, the porous medium with a stiffer solid skeleton can achieve a higher degree of saturation.

Figure 3(a) illustrates the effects of the particle compressibility and of the porosity on the P-wave velocity in fully saturated porous media, where the solid lines are generated using equation (21) (i.e. the particle compressibility is taken into account) and the broken lines are generated using equation (22) (i.e. the particle compressibility is neglected). In computation the shear modulus, $\mu$, is related to $K_s$ using a
common value of Poisson’s ratio, 0·3, and the specific gravity of solid grains is assumed as 2·65.

It is evident from Fig. 3(a) that for porous media with small porosity the difference between the values of $V_p$ given by equations (21) and (22) is very significant and exists over an entire range of the ratio $K_0/K_s$. For porous media of high porosity, however, the difference between the predictions given by equations (21) and (22) becomes less significant, especially at low values of $K_0/K_s$.

In the case of partially saturated porous media with either low or high porosity, the deviation of the value of $V_p$ due to neglect of the particle compressibility is too slight to distinguish, as shown in Fig. 3(b).

The derived explicit expression in equation (25) enables a quantitative identification of the effect of particle compressibility on the relationship between $B$ and $V_p$, as shown in Fig. 4, where the thick lines are obtained with equation (25) and the thin lines are generated by equation (5), a limiting case.
of equation (25). In the same graph the influence of porosity and the skeleton compressibility is also illustrated.

Figure 4(a) indicates that, for porous media of low porosity, the larger the value of \( K_s/K_i \), the more significant the deviation due to neglect of the particle compressibility. For instance, for a rock with \( K_s/K_i = 0.5 \), the predicted value of \( B \) at full saturation is 0.566 by using the general expression in equation (18), and the corresponding \( V_p \) is around 3753 m/s. If the compressibility of solid particles is excluded, the predicted value of \( B \) becomes 0.710 and the corresponding \( V_p \) is as large as 5335 m/s (Table 1).

For porous media of high porosity, the difference caused by ignoring the particle compressibility will become less significant, as shown in Fig. 4(b). But caution should still be exercised, since the difference may still be appreciable at high values of \( K_s/K_i \) (Table 1).

CONCLUDING REMARKS

With the purpose of clarifying the difference between the expressions given by Bishop (1973) and by Kokusho (2000), the pore pressure parameter \( B \) was revisited in this study. It has been shown that Bishop’s expression can also be derived in a rigorous way based on classical Biot’s theory, and the error in the expression by Kokusho (2000) was caused mainly by the incorrect use of the effective stress equation. In the same context of Biot’s theory, a first proposal of the explicit relationship between the pore pressure coefficient, \( B \), and the compressional wave velocity, \( V_p \), has been established. The relationship accounts for the compressibility of solid particles in a consistent way and is applicable to both soils and rocks.

The effects of skeleton compressibility, particle compressibility and porosity have been identified numerically with respect to \( B \) and its relation to \( V_p \). The results indicate that major errors in the value of \( B \) will arise from neglect of the particle compressibility as the skeleton compressibility approaches the compressibility of solid grains, and meanwhile the amount of errors is sensitive to the value of porosity. For porous media of low porosity and low skeleton compressibility, such as rocks, the effect of particle compressibility may be very significant on the values of

both $B$ and $V_p$ at full saturation, whereas for porous media of high porosity and high skeleton compressibility, such as soils, neglect of the particle compressibility leads only to a slightly greater value of $V_p$ but almost the same prediction for $B$.
