## Abstract

The success of liver transplantation has led to an ever-increasing demand for liver grafts. Since the first successful living donor liver transplantation, this surgical innovation has been well established in children and has significantly relieved the crisis of donor organ shortage for children. However, the extension of living donor liver transplantation to adult recipients is limited by the graft volume. The major concern of adult-to-adult living donor liver transplantation is the adequate graft that can be harvested from a living donor. Small-for-size graft injury is frequently observed. To develop novel effective treatments attenuating small-for-size liver graft injury during living donor liver transplantation, it is important to explore the precise mechanism of acute phase small-for-size graft damage. Recently, a number of clinical studies and animal experiments have been conducted to investigate the possible key issues on acute phase small-for-size liver graft injury, such as mechanical injury from shear stress, subsequent inflammatory responses, and imbalance of vasoregulatory factors. This review focuses on the mechanism of small-for-size liver graft injury based on the number of clinical and experimental studies. The latest research findings of the significance of acute phase liver graft injury on late phase tumor recurrence and metastasis are also addressed.

## 1. Background

The emergence of adult-to-adult living donor liver transplantation (ALDLT) over the last decade has led to a dramatic increase in the number of liver grafts available. With a continued shortage of cadaveric donor livers, ALDLT currently offers a significant survival advantage to patients listed for liver transplantation [1]. In single-center series, candidates with potential living related donors are twice as likely to undergo transplantation than those awaiting cadaveric donor grafts, reducing waiting list mortality by half [2,3]. Furthermore, a liver graft from a living related donor allows earlier intervention and lowers dropouts from disease progression, leading to a higher life expectancy [4-6].

A major limitation of ALDLT is the size of the graft that can be safely harvested from the living donor. In an adult recipient, the liver graft from a living related donor is almost always small-for-size. Owing to the reduced liver volume, a small-for-size graft is less effective in coping with the portal flow of an adult recipient. The shear stress from transient portal hypertension causes acute phase mechanical injury [7-9], which subsequently induces severe inflammatory

responses and then has a deleterious effect on the posttransplantation outcome. In spite of rapid hepatic regeneration, small-for-size liver grafts are associated with worse graft function and survival [7-9]. More recently, studies have reported an association between small-for-size liver grafts and higher tumor recurrence after transplantation for hepatocellular carcinoma (HCC) [10-12]. Despite its limitations, the small-for-size graft remains the most promising solution to the severe shortage of liver donors, and the pursuit of its interests should be continued.

Recent evidence has shed new light on the understanding of small-for-size liver graft injury. This review examines the pathogenesis of small-for-size liver graft injury as well as its effect on graft and patient survival. The recent link between small-for-size liver graft injury and tumor recurrence after transplantation for HCC, albeit controversial, will also be discussed.

## 2. The issue of liver graft size

The size of a liver graft selected varies according to the patient, the donor, and the transplant center [13]. In essence, the choice is a delicate balance between donor safety and recipient graft survival. However, as living donors are

 E-mail address: [kwanman@hkucc.hku.hk](mailto:kwanman@hkucc.hku.hk) (K. Man).

61 healthy, their survival is given precedence over graft efficacy  
62 [14]. The normal liver has a large functional reserve. Starzl  
63 et al [15] reported that a minimum residual liver volume of  
64 30% was required for patient survival. Similar results were  
65 reported by Shindl et al [16], where a residual liver volume  
66 of less than 27% was associated with a marked increase in  
67 the incidence of hepatic dysfunction. The ethical preference  
68 for donor safety and a limit on the size of obtainable donor  
69 liver mass explain why, with the exception of pediatric  
70 patients, almost all partial liver grafts are suboptimal in size.

71 At the moment, the extended right liver graft technique  
72 harvests the largest possible liver size (roughly 66% of the  
73 donor liver) [17]. To obtain a graft of suitable size, ALDLT  
74 often mandates the use of donor right hepatectomy. This  
75 procedure has a donor safety profile much less favorable than  
76 left hepatectomy, a large and potentially risky operation in its  
77 own right. [18]. Donor morbidity and mortality are estimated  
78 at 20% [19] and 0.5% [20], respectively, which have been  
79 confirmed by a recent series [21].

### 80 3. Definition of the small-for-size graft

81 An accepted definition of the small-for-size graft has not  
82 been established within the transplantation community.  
83 There are currently 2 schools of thought.

84 Small-for-size liver grafts can be classified as those with  
85 graft weight to estimated standard liver weight ratio of less  
86 than 40% [22–24]. Grafts below the critical size are  
87 associated with poor early graft function and a marked  
88 reduction in graft and patient survival after transplantation  
89 [13]. Alternatively, the definition of small-for-size liver  
90 grafts can be extended to include all grafts smaller than the  
91 standard liver volume (calculated using the formula by Urata  
92 et al [25]) [26].

93 The former definition focuses on grafts with unacceptable  
94 survival, whereas the latter classifies virtually all liver grafts  
95 from living related donors as small-for-size [27]. Because of  
96 the increasing evidence that size-related injury extends  
97 beyond grafts less than 40% of the standard liver weight, the  
98 latter definition is preferred because it represents a more  
99 complete picture of the pathologic process. The cohort  
100 described by the former will be referred to as marginal grafts.

### 101 4. Small-for-size liver graft injury

102 Small-for-size liver graft injury refers to the insult related  
103 to the small size of the graft in addition to ischemia/  
104 reperfusion injury [27]. The initiating event is transient  
105 portal hypertension after reperfusion due to graft size  
106 mismatch [7,28]. High portal pressure causes mechanical  
F1 107 damage to the hepatic sinusoids (Fig. 1), which in turn leads  
108 to tissue ischemia, imbalance of vasoregulatory factors,  
109 increase in free radical formation, and exaggerated inflam-  
110 matory response. The consequence of small-for-size liver

graft injury is dependent on the extent of damage, which is 111  
inversely proportional to the graft size. The possible 112  
mechanism of small-for-size liver graft injury was summar- 113  
ized in Fig. 2. 114 F2

#### 115 4.1. Transient portal hypertension

116 The liver has 2 major sites of vascular inflow: the portal 116  
vein and the hepatic artery. Although portal blood flow 117  
undergoes very little autoregulation within the liver, a 118  
buffer system is in place to prevent excessive blood flow 119  
from damaging the liver. An increase in portal pressure can 120  
be countered by the hepatic arterial buffer response, where a 121  
change in portal flow induces reciprocal effects on arterial 122  
flow [29]. Through this buffer system, a liver can tolerate a 123  
maximum of 20% increase in blood flow [30]. Such a buffer 124  
system is present after transplantation [31] but is not enough 125  
to compensate for the mismatched portal flow in small-for- 126  
size grafts [32]. Because the portal flow destined for a 127  
whole liver is directed through a partial liver, excessive 128  
portal pressure is built up in small-for-size grafts, resulting 129  
in portal hypertension. The increase in portal pressure due 130  
to graft size mismatch is transient in nature and lasts for 30 131  
minutes after reperfusion. 132

133 Shear stress from the transient portal hypertension 133  
inflicts mechanical damage upon the hepatic sinusoidal 134  
endothelium. Using a novel porcine liver transplantation 135  
model, Kelly et al [33] demonstrated an inverse relationship 136  
between the graft size and the extent of hepatic sinusoidal 137  
injury. The presence of severe sinusoidal injury was 138  
reported in grafts with an estimated standard liver volume 139  
(ESLV) of 20% or less. The damage was less severe in 140  
grafts with an ESLV of 30% and was further lessened in 141  
grafts with an ESLV of 60%. Damage was virtually 142  
nonexistent in whole grafts [28]. 143

#### 144 4.2. Severer ischemia injury

145 Being the principle vessels involved in transvascular 145  
exchange between the blood and the liver parenchymal cells, 146  
the sinusoids are critical in the maintenance of hepatic 147  
functions [28]. A healthy microcirculatory environment is 148  
vital to the recovery of graft function after reperfusion 149  
[34,35]. Injury to the sinusoidal cells results in sinusoidal 150  
stasis and congestion [36], and a lack of functional 151  
microcirculation exposes the liver tissue to ischemia [37]. 152  
Although the hemodynamic changes are transient, tissue 153  
ischemia secondary to sinusoidal insult causes progressive 154  
cellular damage. The histologic hallmarks of prolonged 155  
ischemia include swelling of mitochondria and hepatocytes 156  
as well as presence of apoptosis [28]. 157

#### 158 4.3. Imbalance of vasoregulatory peptides

159 In the normal liver, the maintenance of hepatic micro- 159  
circulation relies heavily on the delicate balance of vasocon- 160  
striction and vasodilatation. Prolonged ischemia from 161  
sinusoidal damage tips the balance in favor of vasoconstriction 162

Fig. 1. Hepatic ultrastructural changes after liver transplantation in animal (A) and human (B) studies. A, Tremendous mitochondrial swelling with unvisualized cristae (\*) was found in the hepatocytes. Collapse of the Disse space (arrow) and an irregular large gap (arrow head) between the sinusoidal lining cells also occurred. Total disruption of hepatic sinusoidal lining cells (arrows) was presented at 24 hours after reperfusion in animal study (animal study from Man et al [28]; human study from Man et al [7]).

163 [7]. The gene for endothelin 1 is overexpressed as a result of  
 164 ischemia, resulting in its overproduction [38]. Endothelin 1 is  
 165 the most potent constrictor peptide of vascular smooth muscle

[39] and increases intrahepatic resistance by directly constricting  
 the remaining hepatic sinusoids. On the other hand, the  
 gene for endothelial nitric oxide synthase is underexpressed.

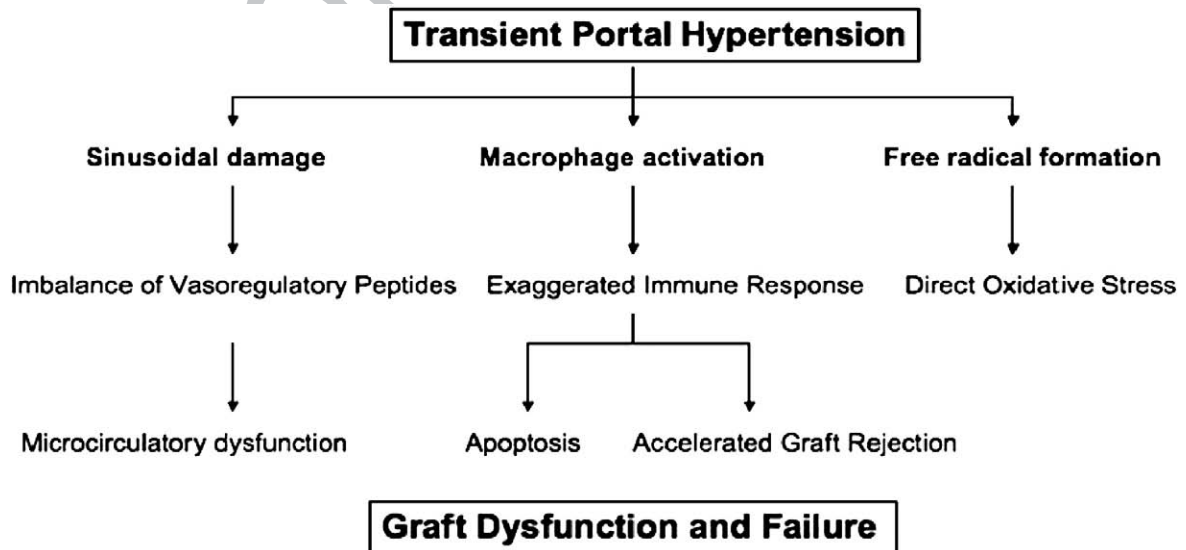

Fig. 2. Pathways to small-for-size liver graft injury.

169 Endothelial nitric oxide synthase is involved in the main-  
 170 tenance of vasodilatation through the production of endogen-  
 171 ous nitric oxide [40]. Endogenous nitric oxide in turn is vital in  
 172 the physiological regulation of blood flow [41]. This results in  
 173 a further shift of balance toward vasoconstriction.

174 Furthermore, genes for heat shock protein 70 and heme  
 175 oxygenase 1, which are important for tissue repair [42] and  
 176 protection against vascular constriction [43], respectively,  
 177 are also underexpressed in small-for-size grafts. A shift  
 178 toward vasoconstriction results in further ischemic damage.

#### 179 4.4. Increase in free radical formation

180 The production of free radicals is markedly increased in  
 181 small-for-size grafts shortly after reperfusion [44]. Zhong et al  
 182 [44] suggested 2 possible mechanisms of free radical  
 183 formation in small-for-size grafts. First, a reduction in graft  
 184 size increases the metabolic burden on the graft. As  
 185 metabolism increases, mitochondria produce more oxygen  
 186 radicals. At the same time, reduced glutathione, a potent  
 187 antioxidant, is consumed more rapidly in smaller grafts. The  
 188 result is a net increase in free radicals and more severe graft  
 189 injury [45]. A second explanation involves Kupffer cells. Each  
 190 individual Kupffer cell in a small-for-size graft is exposed to  
 191 higher amounts of endotoxin than that in a whole liver graft  
 192 [46]. In turn, the exposure to endotoxin triggers Kupffer cells  
 193 to release a large quantity of free radicals. Regardless of the  
 194 method of release, the free radicals cause direct oxidative  
 195 damage to the remaining hepatocytes and sinusoids. An  
 196 increase in free radical formation is associated with increased  
 197 graft injury and worse graft function, as indicated by increased  
 198 serum alanine transferase and bilirubin levels as well as  
 199 histologic signs of necrosis and leukocyte infiltration.

#### 200 4.5. Exaggerated inflammatory response

201 A common finding in liver grafts after transplantation is a  
 202 cellular infiltrate secondary to ischemia/reperfusion injury.  
 203 The cellular infiltrate predominantly consists of macro-  
 204 phages. As a result of transient portal hypertension, the  
 205 macrophage cell number and activity are substantially  
 206 increased in small-for-size grafts. Using a rat liver  
 207 transplantation model, Yang et al [47] demonstrated a  
 208 significantly higher macrophage infiltrate in the periportal  
 209 area of small-for-size grafts compared with that of whole  
 210 grafts during early phase after reperfusion. The number of  
 211 macrophages expanded to reach a peak at 72 hours after  
 212 reperfusion. In addition to an increase in the cell number, the  
 213 activity of the macrophages was also enhanced in small-for-  
 214 size liver grafts. This was represented by exaggerated  
 215 expression of inducible nitric oxide synthase by the  
 216 macrophages in small-for-size grafts.

217 The invading macrophages in small-for-size grafts secrete  
 218 high levels of cytokines, specifically interleukin 1 $\beta$  and  
 219 interleukin 2, during early phase after reperfusion. In the in  
 220 vitro setting, Yang et al [47] demonstrated that interleukin 1 $\beta$   
 221 transforms macrophages into antigen-presenting cells, as

222 evidenced by the expression of CD80 and CD86. These 2  
 223 molecules provide vital stimuli to prime T cells against  
 224 antigens presented by antigen-presenting cells. The presence  
 225 of a larger number of antigen-presenting cells in small-for-  
 226 size grafts enhances alloantigen recognition and subse-  
 227 quently results in accelerated graft rejection.

228 In a separate study by Yang et al [48], vascular endothelial  
 229 growth factor (VEGF) was put forward as the vital link  
 230 between transient portal hypertension and macrophage  
 231 activation in small-for-size grafts. Microcirculatory injury  
 232 after reperfusion triggers VEGF secretion from hepatocytes,  
 233 a vital physiological process needed for rapid hepatic  
 234 regeneration. However, VEGF is also an important mediator  
 235 of monocyte and activities, and excessive VEGF is produced  
 236 in small-for-size grafts because of more profound micro-  
 237 circulatory damage. Subsequently, an increase in production  
 238 of intragraft VEGF results in the enhancement of migratory  
 239 activities of monocytes in small-for-size grafts [48].

## 240 5. Clinical consequence of small-for-size liver 241 graft injury

242 The most severe consequence of small-for-size liver graft  
 243 injury is small-for-size syndrome, defined as graft dysfunc-  
 244 tion or graft failure during the first postoperative week after  
 245 the exclusion of other causes [49]. This syndrome is almost  
 246 exclusive to marginal grafts. Several notable studies have  
 247 reported different cutoff points for marginal grafts. Kawa-  
 248 saki et al [50] set the limit of safe liver graft size at 30% of  
 249 ESLV. This threshold point is shared by Nishizaki et al [51].  
 250 Lo et al [52] reported that graft sizes below 40% of ESLV  
 251 have low success rates. Lee et al [72] used a graft-recipient  
 252 weight ratio (GRWR) of less than 0.8% as the limit, whereas  
 253 Ben-Haim et al [53] reported that a GRWR as low as 0.6%  
 254 is suitable for patients with less severe end-stage liver  
 255 disease. It is important to note, however, that these limits are  
 256 mainly arbitrary.

257 Small-for-size syndrome is attributable solely to size of the  
 258 graft because not every marginal graft results in dysfunction  
 259 or failure. Small-for-size syndrome is a multifactorial disease.  
 260 Other factors involved in small-for-size syndrome include  
 261 graft-related causes (a lack of liver regeneration [54], high  
 262 portal inflow [55], low venous outflow [56], preexisting  
 263 steatosis in the donor [57]), and recipient-related causes  
 264 (severe preoperative end-stage liver disease [53], presence of  
 265 cirrhosis [58], and poor preoperative health status).

266 For small-for-size liver grafts with GRWR of more than  
 267 0.8%, a difference in survival compared with whole liver  
 268 grafts is less convincing. Earlier reports on short-term  
 269 survival after liver transplantation suggested poorer graft  
 270 survival in ALDLT recipients. Using the United Network for  
 271 Organ Sharing data in a retrospective analysis, Abt et al [8]  
 272 discovered a significantly higher rate of allograft failure in  
 273 ALDLT recipients compared with deceased donor liver  
 274 transplantation (DDLTL) recipients (hazards ratio, 1.66;

confidence interval, 1.30–2.11). With the same database, Thuluvath and Yoo [9] reported a 2-year graft survival of 64.4% in ALDLT recipients compared with 73.3% in the DDLT recipients. The difference in graft survival between the 2 groups was statistically significant. However, because of the availability of retransplantation for recipients who developed allograft failure, patient survival after ALDLT remained similar to that of DDLT. A crucial limitation of the United Network for Organ Sharing database is omission of data on graft size. It is impossible to confirm whether size plays a role in the poorer graft survival.

A more recent study on long-term survival after liver transplantation refutes previous evidence of poorer survival in ALDLT recipients. Maluf et al [59] found no statistical differences between ALDLT and DDLT in the patient or graft survival rates at 5 years after transplantation. A possible reason for the discrepancy in results is an improvement of surgical technique at a high volume center. Results from our center also demonstrated a lack of significant difference in patient and graft survival between the 2 groups. With a median follow-up time of 27 months, the graft and patient survival rates were 88% and 90%, respectively, in the ALDLT group, whereas the survival rates were both 84% in the DDLT group. In this study, the ALDLT grafts had a significantly lower median graft weight to estimated standard liver weight ratio (48.9% vs 98.2%). Liu et al [46] cited that their regular inclusion of the middle hepatic vein in partial liver grafts, which allows good venous drainage to meet the high metabolic demand of recipients, might have resulted in the more favorable survival outcomes in ALDLT.

## 6. Small-for-size liver graft injury on late phase tumor recurrence

### 6.1. Background

Although ALDLT confers a substantial survival advantage for patients with HCC awaiting transplantation, the preference of ALDLT to DDLT is based primarily on hypothetical studies using decision analysis models [4,5]. Such studies assume comparable tumor recurrence rates and patient survival after ALDLT and DDLT. With the adoption of the Milan criteria, DDLT offers a tumor recurrence rate of less than 10% [60]. This in turn confers a patient survival rate comparable to patients undergoing DDLT without HCC (75% survival at 4 years) [61,62]. In comparison, the tumor recurrence rate after ALDLT remains controversial.

### 6.2. Clinical evidence of inferior oncologic outcome

Recently, a number of centers have compared the outcomes of ALDLT and DDLT using retrospective clinical data. The inability to conduct a randomized controlled trial has led to conflicting results in different centers. However,

there is increasing evidence that partial liver grafts lead to higher tumor recurrence after ALDLT for HCC.

On one hand, Hwang et al [63] reported no significant difference in the HCC recurrence rates between the 2 cohorts. Instead, tumor size, gross major vessel invasion, and histologic differentiation were cited as the major risk factors for tumor recurrence. Gondolesi et al [64] also observed comparable tumor recurrence rates between ALDLT and DDLT.

On the other hand, an increasing amount of evidence points to a higher tumor recurrence rate after transplantation using ALDLT. In 2004, Kulik et al [12] reported higher HCC tumor recurrence rates in the “fast tracked” ALDLT cohort (22%) compared with the DDLT cohort (3%). They reasoned that the shorter waiting time did not allow an adequate period to assess the tumor’s biological behavior. Hence, the ALDLT group included more aggressive tumors, which may have accounted for the higher tumor recurrence rate. However, the team also hypothesized that, by virtue of its relatively small size, the liver graft from a living donor could potentially promote tumor growth and metastasis independently and, thus, result in a higher tumor recurrence rate. This theory has become the focus of more recent studies on the topic.

In 2007, Lo et al [11] reported a 5-year recurrence rate of 22% in the ALDLT cohort and a 5-year recurrence rate of 0% in the DDLT cohort. In the study, tumor recurrence was the major cause of death after transplantation, with 6 of the 10 deaths attributable to tumor recurrence [11]. Furthermore, the 5-year patient survival rate was substantially lower in the ALDLT cohort (58% vs 94%), which, however, without statistical significance, was most likely because of the small sample size. In the same year, the multicenter Adult-to-Adult Living Donor Liver Transplantation Cohort Study reported a 3-year higher tumor recurrence rate in the ALDLT cohort (29% vs 0%) [10]. This time, however, there was little difference in the overall patient survival of the 2 groups. A striking similarity in the 2 studies was the lack of tumor recurrence in the DDLT cohort. The finding that even transplantation for tumors outside the Milan and University of California, San Francisco, criteria lacked recurrence suggested that factors other than tumor aggressiveness before transplantation were responsible for the findings. Again, both studies proposed that the small size of the living donor liver graft was potentially responsible for the higher recurrence rate. However, the hypothesis yet remains unproven.

Most recently, Hwang et al [65] tested the effect of GRWR on tumor recurrence with a retrospective study on past transplantations. The study found no statistical differences in the overall patient survival ( $P = .105$ ) and recurrence-free survival ( $P = .406$ ) among grafts with GRWR less than .8 (small grafts), GRWR of .8–1.0 (mid sized), GRWR greater than 1.0 (large sized), and those with GRWR greater than 1.5 (whole grafts). However, because of a high amount of sample stratification, the sample size of each group and, hence, the power were not large enough to detect a statistical difference. Table 1 shows the results of the aforementioned studies. In the face of such controversy, an

t1.1 Table 1

t1.2 Tumor recurrence after liver transplantation using DDLT and LDLT

Q2

381 in-depth examination on the molecular aspect of the topic  
382 is necessary.

383 6.3. Molecular pathways linking small-for-size liver graft  
384 injury to tumor recurrence after transplantation for HCC

385 Crucially, there is an overlap of processes in small-for-  
386 size graft injury with those involved in tumor invasion. Such

387 factors may provide a favorable environment for tumor  
388 recurrence in small-for-size grafts.

389 The main pathway in which the outgrowth of preexisting  
390 micrometastases can be promoted in small-for-size grafts is  
391 through tissue ischemia. It is present in small-for-size grafts  
392 secondary to portal hyperperfusion injury. The ischemia is  
393 exacerbated by the hepatic arterial buffer response because it  
394 leads to a decrease in hepatic arterial flow. In a study by Doi

Fig. 3. A, Liver tumor development after liver transplantation using whole or small-for-size liver grafts at day 14 and day 21. B, The liver occupied by tumor was compared at different time points. C, Liver tumor growth in nude mice at week 4 and week 6 after tumor implantation from group W or group S. D, The volume of tumors from nude mice was also compared. \* $P < .05$  group W vs group S. (From Man et al., *Ann Surg*, in press).

Q3

395 et al [66], prolonged liver ischemia induced higher secretion  
 396 of inflammatory cytokines, increased free radical formation,  
 397 and subsequently increased liver metastasis of colon cancer.  
 398 van der Bilt et al [67] reported that ischemic lobes in murine  
 399 livers had a 5-fold to 6-fold increase in outgrowth of  
 400 micrometastases compared with nonischemic lobes. The  
 401 same study also discovered that a decrease in ischemic time  
 402 would drastically decrease the incidence of metastasis.

#### 403 6.4. Liver graft injury and tumor recurrence

404 Recently, we have demonstrated the significance of  
 405 surgical stress on tumor behavior in a rat liver tumor model  
 406 undergoing ischemia/reperfusion injury and major hepatectomy.  
 407 The surgical stress resulting from hepatic  
 408 ischemia/reperfusion injury and/or major hepatectomy did  
 409 not only make the hepatic microenvironment (“soil”)  
 410 favorable for tumor cell growth, migration, and invasion  
 411 through stimulation of acute phase inflammatory response  
 412 and disturbance of microcirculatory barrier function but  
 413 also made the tumor cells (“seeds”) more aggressive for  
 414 local and distant metastases by directly activating cell  
 415 migration and invasion pathways in the tumor cell itself  
 416 [68]. We also demonstrated the significance of graft size in  
 417 tumor growth and invasiveness after liver transplantation in  
 418 a rat model. More rapid and invasive tumor development in  
 419 small-for-size liver grafts was evident in morphological  
 420 examination and was supported by the signaling linking to  
 421 angiogenesis and tumor invasiveness. We further confirmed  
 422 the invasiveness of tumors developed from small-for-size  
 423 grafts in a novel orthotopic nude mice implantation model  
 424 (Fig. 3) [69]. It was found that acute phase small-for-size

425 liver graft injury does not only provide a microenvironment  
 426 that favors tumor development but also promotes the  
 427 invasiveness of tumor cells.

428 The small liver remnants and small-for-size liver graft  
 429 expressed significantly high levels of early overexpression of  
 430 early growth response 1, focal adhesion kinase, and VEGF  
 431 [68,69]. Early growth response 1 switches on several  
 432 cascades of inflammatory response as well as angiogenesis  
 433 and cell adhesion [70]. The activation of focal adhesion  
 434 kinase is related to microvascular barrier dysfunction and has  
 435 been demonstrated to promote an invasive tumor cell  
 436 phenotype [71]. Vascular endothelial growth factor is a  
 437 major promoter of angiogenesis [72].

438 From the studies, there are several possible mechanisms  
 439 in which small-for-size liver graft injury can increase the  
 440 incidence of tumor recurrence. They may include increase in  
 441 cell adhesion factors, liver parenchyma damage/microvas-  
 442 cular barrier dysfunction, and angiogenesis.

#### 443 6.5. Cell adhesion

444 Prolonged ischemia is associated with higher expression  
 445 of E-selectin and, consequently, a higher incidence of tumor  
 446 metastasis [73]. E-selectin is a molecule that is important in  
 447 inflammatory responses [74] because it facilitates the  
 448 adhesion of leukocytes to endothelial cells [75]. It is also  
 449 reportedly involved in liver cancer growth and metastasis  
 450 [76] by facilitating the adhesion of cancer cells to the  
 451 endothelium [77]. Expression of E-selectin increases with the  
 452 length of ischemic period. This is because E-selectin is up-  
 453 regulated by tumor necrosis factor  $\alpha$  and interleukin 1 [78],  
 454 whose expression is in turn promoted by liver ischemia

Fig. 4. Possible mechanism of invasive tumor growth after transplantation using small-for-size grafts.

455 [79]. It is also possible that other adhesion molecules  
456 expressed during ischemia may have similar effects on  
457 tumor recurrence.

#### 458 6.6. Microvascular dysfunction

459 Apoptosis is the most important mechanism of ischemia-  
460 induced cell death and was shown by van der Bilt et al [67] to  
461 be also important in tumor metastasis. Liver ischemic injury  
462 induces areas of apoptosis, resulting in infiltration of  
463 lymphocytes into the area. Areas of necrosis then develop  
464 in the liver parenchyma. This facilitates the growth of tumor  
465 cells [67] as they preferentially invade into zones surround-  
466 ing tissue necrosis.

#### 467 6.7. Angiogenesis

468 Vascular endothelial growth factor, as mentioned  
469 previously, is a major angiogenic factor and is up-regulated  
470 by tissue hypoxia secondary to microvascular dysfunction.  
471 Previous studies demonstrated the ability of VEGF to  
472 induce angiogenesis in cerebral ischemia [72]. Vascular  
473 endothelial growth factor was also reported to be important  
474 in ischemic wound healing [80]. A crucial study discovered  
475 a direct correlation between vascular clamping time and  
476 intrahepatic VEGF levels [81], which led to a less favorable  
477 oncologic outcome in these patients. As Yang et al [48]  
478 reported an increase in VEGF expression in small-for-size  
479 grafts, it is possible that small-for-size graft injury-induced  
480 ischemia may result in VEGF overexpression and, conse-  
481 quently, angiogenesis.

482 In summary, although partial liver grafts provide earlier  
483 transplantation and lowers waiting list mortality, the major  
484 concern is posttransplantation survival. Small-for-size liver  
485 graft injury is virtually present in all partial liver grafts. It is a  
486 multistep detrimental process reinforced by strong collat-  
487 erals. The process begins with transient portal hypertension  
488 due to graft size mismatch, which inflicts mechanical  
489 damage on the hepatic sinusoidal endothelium. Dysfunction  
490 of the hepatic sinusoidal endothelium results in global  
491 ischemia to the liver graft, which triggers a cascade of  
492 vasoconstriction, free radical production, and monocyte  
493 migration to the liver graft. The consequence is acute phase  
494 graft injury. The extent of damage and graft dysfunction is  
495 dependent on the size of the partial liver graft. Clinical  
496 studies have, however, demonstrated that with good surgical  
497 technique and the use of grafts with graft weight to estimated  
498 standard liver weight ratio greater than 40%, acute graft  
499 failure can be minimized to levels comparable with whole  
500 liver grafts. Further evidence though is needed for  
501 comparison of the long-term outcome (>5 years).

### 502 7. Conclusions

503 Acute phase small-for-size graft injury may not only  
504 affect short-term graft survival but may also contribute to late

phase tumor recurrence and metastasis in liver transplanta- 505  
tion for liver cancer (Fig. 4). An improved understanding of 506 F4  
small-for-size liver graft injury will facilitate preventive and 507  
therapeutic measures not only for early graft dysfunction but 508  
also for late phase tumor recurrence and metastasis. 509
